ABSTRACT Hydrogen ions are important regulators of ion flux through voltage-gated Ca\textsuperscript{2+} channels but their site of action has been controversial. To identify molecular determinants of proton block of L-type Ca\textsuperscript{2+} channels, we combined site-directed mutagenesis and unitary current recordings from wild-type (WT) and mutant L-type Ca\textsuperscript{2+} channels expressed in Xenopus oocytes. WT channels in 150 mM K\textsuperscript{+} displayed two conductance states, deprotonated (140 pS) and protonated (45 pS), as found previously in native L-type Ca\textsuperscript{2+} channels. Proton block was altered in a unique fashion by mutation of each of the four P-region glutamates (E\textsubscript{I}-E\textsubscript{IV}) that form the locus of high affinity Ca\textsuperscript{2+} interaction. Glu(E) → Gln(Q) substitution in either repeats I or II abolished the high-conductance state, as if the titration site had become permanently protonated. While the E\textsubscript{I}Q mutant displayed only an ~40 pS conductance, the E\textsubscript{III}Q mutant showed the ~40 pS conductance plus additional pH-sensitive transitions to an even lower conductance level. The E\textsubscript{IV}Q mutant exhibited the same deprotonated and protonated conductance states as WT, but with an accelerated rate of deprotonation. The E\textsubscript{I}Q mutant was unusual in exhibiting three conductance states (~145, 102, 50 pS, respectively). Occupancy of the low conductance state increased with external acidification, albeit much higher proton concentration was required than for WT. In contrast, the equilibrium between medium and high conductance levels was apparently pH-insensitive. We concluded that the protonation site in L-type Ca\textsuperscript{2+} channels lies within the pore and is formed by a combination of conserved P-region glutamates in repeats I, II, and III, acting in concert. E\textsubscript{IV} lies to the cytoplasmic side of the site but exerts an additional stabilizing influence on protonation, most likely via electrostatic interaction. These findings are likely to hold for all voltage-gated Ca\textsuperscript{2+} channels and provide a simple molecular explanation for the modulatory effect of H\textsuperscript{+} ions on open channel flux and the competition between H\textsuperscript{+} ions and permeant divalent cations. The characteristics of H\textsuperscript{+} interactions advance our picture of the functional interplay between P-region glutamates, with important implications for the mechanism of Ca\textsuperscript{2+} selectivity and permeation.

INTRODUCTION

Extracellular pH falls sharply during episodes of intense neuronal activity (Chesler and Kaila, 1992) or with ischemia in brain or heart (Katz, 1992; Siejo et al., 1993). The change in \(pH_\text{e}\) has a significant effect on many kinds of ion channels (Hille, 1992; Traynelis, 1996). However, the mechanism of pH-dependent control of channel function is not completely understood at the molecular level. Voltage-gated calcium channels are particularly interesting targets of hydrogen ion regulation because of their biological importance as a delivery system for a key intracellular messenger. Increased \([H^+]\) strongly inhibits ion permeation through open Ca\textsuperscript{2+} channels as well as reducing channel opening (Prod'hom et al., 1987; Krafte and Kass, 1988; Klöckner and Isenberg, 1994). The inhibitory effect of extracellular acidification on voltage-gated Ca\textsuperscript{2+} channels helps limit Ca\textsuperscript{2+} overload and subsequent damage during a metabolic insult (e.g., Ou-Yang et al., 1994).

The interaction between protons and Ca\textsuperscript{2+} channels also shows intriguing biophysical properties. Recordings of unitary currents through L-type Ca\textsuperscript{2+} channels by the late Peter Hess and colleagues provided the first direct measurements of the protonation/deprotonation rates of a single molecule (Prod'hom et al., 1987). When probed with various monovalent cations as charge carriers, these channels were protonated at a single site with an anomalously high affinity for H\textsuperscript{+} (pK\textsubscript{a} > 7.0), resulting in an unusual subconductance state (Prod'hom et al., 1987; Pietrobon et al., 1989; Prod'hom et al., 1989). Protons also reduced the unitary fluxes of Ca\textsuperscript{2+} and other divalent cations, although much greater acidification was required for block (Krafte and Kass, 1988; Kuo and Hess, 1993; Klöckner and Isenberg, 1994).

Despite extensive study, disagreement remains about the locus of H\textsuperscript{+} block of Ca\textsuperscript{2+} channels and the mechanism of inhibition of ion flux. In the prevailing hypothesis, Hess and colleagues proposed that protons titrate an external histidine residue, outside of the permeation pathway, and reduce channel conductance by an allosteric mechanism (Pietrobon et al., 1989). Mutagenesis studies have provided direct support for such an allosteric mechanism in the case of proton block of...
inward rectifier K⁺ channels (Coulter et al., 1995). However, an alternative possibility of H⁺ block of Ca²⁺ channels is that the protonation site resides within the pore itself and that ion movements are reduced by a straightforward blocking mechanism (Kuo and Hess, 1993). This hypothesis gains plausibility by analogy to cyclic nucleotide gated (CNG) channels (Root and MacKinnon, 1994). H⁺ block of CNG channels involves glutamates in the pore-forming region (Root and MacKinnon, 1994), homologous to residues that form the high-affinity Ca²⁺ binding site in Ca²⁺ channels (Kim et al., 1993; Tang et al., 1993; Yang et al., 1993; Ellinor et al., 1995).

We set out to resolve these questions, using a combination of site-directed mutagenesis and single channel recordings from Xenopus oocytes expressing wild-type (WT) and mutated L-type Ca²⁺ channels. Our experiments provided direct evidence that protons block the Ca²⁺ channel by interacting with a site along the permeation pathway, rather than an external regulatory site outside of the pore. The observations allowed us to identify a specific subset of P-region glutamates that make up the protonation site and led to a simple explanation of how carboxylate side chains of these glutamates work in concert to form a single titration site with extremely high H⁺ affinity. The proton interactions gave fresh perspective on the asymmetrical disposition of the P-region glutamates, and their possible conformational flexibility, relevant to fundamental mechanisms of Ca²⁺ channel selectivity and ion permeation.

**METHODS**

**Expression of the Wild-type and Mutant L-type Ca²⁺ Channels in Xenopus Oocytes**

L-type channels were expressed in Xenopus oocytes in the subunit combination α₁Cβ₂α₂δ as described previously (Yang et al., 1993; Ellinor et al., 1995). Briefly, the corresponding cRNAs were generated by in vitro transcription using rabbit clones for α₁C (Mi- kami et al., 1989), β₂ (Hullin et al., 1992), and α₂ (Mi- kami et al., 1989), and coinjected in Xenopus oocytes in approximately equal molar ratio. Expression of the L-type Ca²⁺ channels was confirmed by the appearance of FPL 64176-sensitive Ba²⁺ current in whole oocyte recordings using the two-electrode voltage clamp. The experiments were usually performed 4–5 d after the cRNA injection. The single glutamate to glutamine mutations in the P-region of L-type Ca²⁺ were generated as previously described by Yang et al. (1993). Using the original constructs (Yang et al., 1993), single channel recordings for several mutants were difficult due to the relatively low density of L-type channels expressed on the sur-
tial $H \leftrightarrow M \leftrightarrow L$ model. Thus, direct $H$-$L$ transitions cannot be completely excluded but certainly do not occur frequently.

**RESULTS**

Clear Resolution of Individual Protonation Events in Expressed L-type Channels
cRNAs encoding L-type $\text{Ca}^{2+}$ channels were coinjected into *Xenopus* oocytes as the subunit combination $\alpha_{1C}\beta_{2}\delta$, and unitary current recordings were obtained using the cell-attached patch configuration 4–7 d after cRNA injection. Fig. 1 shows proton block of the expressed L-type $\text{Ca}^{2+}$ channels, recorded with monovalent cations as current carriers. Consistent with published observations with native L-type channels (Prod'hom et al., 1987), the single channel current displayed fast flickery transitions between high conductance and low conductance levels when $\text{Na}^+$ was used as a charge carrier at pH 7.4 (Fig. 1A, top). The previous results indicated that these transitions correspond to binding and unbinding of individual protons to the L-type channel, with the high and low conductance levels corresponding to deprotonated and protonated states of the channel respectively (Prod'hom et al., 1987). Deviations from the predictions of the simple blocking model have been reported (Pietrobon et al., 1989; Prod'horn et al., 1989), but they most likely result from participation of the buffer in the proton transfer reaction, as was recently shown for proton block of the cyclic nucleotide-gated channels (Root and MacKinnon, 1994). Thus, in the following analysis, pH-dependent transitions between two conductance levels of L-type channel will be interpreted as transitions between protonated and deprotonated states of the channel, in accordance with a simple blocking mechanism.

The resolution of the two conductance states in our experiments was improved when $H^+$ was replaced by $^3\text{H}^+$, a heavier hydrogen ion, due to the isotope effect (Fig. 1A, middle; see Prod'horn et al., 1987). Substitution of $K^+$ for $\text{Na}^+$ as a charge carrier also slowed down the transitions between these two states (data not shown; Pietrobon et al., 1988). Since we anticipated that some of the L-type channel mutants might produce severe changes in block or unblock rates, we chose to use these effects in combination to optimize the recording conditions for kinetic analysis. Thus, most of our experiments were performed with $K^+\cdot^2\text{H}_2\text{O}$ (Fig. 1A, bottom). The average time in the protonated state in $K^+\cdot^2\text{H}_2\text{O}$ was two to threefold longer than that measured in $K^+\cdot\text{H}_2\text{O}$, and greater than fivefold longer than that found with $\text{Na}^+\cdot\text{H}_2\text{O}$. Under these conditions, the individual protonation/deprotonation events were clearly evident as abrupt transitions in the amplitude of the single channel current.
When the external pH was varied from 7.5 to 9.75, progressive changes were seen in the balance between the high conductance (deprotonated) level and the low conductance (protonated) level (Fig. 1 B). Lowering the proton concentration decreased the proportion of time spent in the low conductance state and increased the preponderance of the high conductance state, while not significantly affecting the unitary current amplitude at either level (Fig. 1 B, right). The slope conductances of the deprotonated and protonated states were 140 ± 23 pS, n = 4 and 45 ± 11 pS, n = 4 over the range between -120 and -50 mV (Fig. 2 C).

To describe the proton block quantitatively, the open-state all-points amplitude histograms were fitted with the sum of two Gaussian functions (Fig. 1 B, right, solid curves). The unfitted data points between the peaks are due in large part to poorly resolved fast transitions between the blocked and unblocked states. The percentage of block was estimated from the relative areas of the peaks corresponding to protonated (lower conductance) and deprotonated (high conductance) states. The average percentage of time spent in the deprotonated state was 17 ± 2% (n = 4) at pH 7.5; 53 ± 1.5% (n = 4) at pH 8.5; 85 ± 5% (n = 2) at pH 9.75 (Fig. 3 C, WT). These data are consistent with the presence of a single protonation site with pK_a ~8.5 under our experimental conditions. Thus, proton block of L-type Ca^{2+} channels expressed in Xenopus oocytes (Fig. 1) shares major similarities with that described in guinea pig ventricular myocytes and PC-12 cells (Prod'hom et al., 1987; Pietrobon et al., 1988; Pietrobon et al., 1989; Prod’hom et al., 1989).

**Elimination of the High Conductance State in EIQ and EIIIQ Mutants**

To determine whether protonation involves residues within the pore, we analyzed changes in single channel behavior arising from mutations in individual P-region glutamates. We focused on glutamine replacements because they are isosteric and can be regarded as functionally equivalent to permanent protonation. If the protonation site of L-type channels were indeed formed by P-region glutamates, then at least some of the E → Q mutations should reduce the single channel current by simulating the protonation of the wild-type channel and alter or occlude the effect of acidic pH by interfering with any additional protonation. These predictions were borne out by the E → Q mutation in repeat I (EIQ), which induced a dramatic change in channel properties (Fig. 2 A). Only one current level was apparent in this mutant, the current amplitude histogram conforming to a single Gaussian distribution at either pH 7.5 or 8.5. The corresponding slope conductance was 37 ± 2.5 pS (n = 4) over the range between -120 and -50 mV, in good agreement with the slope conductance of the protonated state of the wild-type channel (Fig. 2 C). This result was not restricted to the use of K^+ as a current carrier, as similar observations were made using Na^+ (data not shown). Thus, the EIQ mutation not only mimics the effect of protonation on wild-type channel conductance, but also prevents external H^+ from binding to its native site over the pH range tested.

Neutralization of the glutamate in repeat III (EIIIQ) also abolished the high conductance level that had been observed in the wild-type channel (Fig. 2 B). The major current level for the EIIIQ mutant was characterized by a conductance of 42 ± 3 pS (n = 3), similar to the value for EIQ and the low conductance level of...
wild-type channels (Fig. 2 C). However, unlike EIQ, EIIIQ also displayed fast flickery transitions toward an even lower but apparently non-zero current level that was very small (<1 pA at -100 mV) and readily confused with channel closures due to gating. Examination of current records obtained at -120 and -140 mV confirmed the existence of a lower conductance state (data not shown). Because of this additional level, two Gaussian functions were required to fit the open channel, all-points amplitude histogram of EIIIQ mutant (Fig. 1 B). Since the relative areas of the corresponding peaks were affected by variation of external pH (Fig. 2 B), we concluded that transitions to the lower conductance level in EIIIQ mutant correspond to protonation events. The pK_a appeared to be <7.5 because even at this pH, channels spend <50% of the time in the protonated state. Evidently, the EIIIQ mutation mimics the effect of normal protonation on the single channel conductance for monovalent cations, without eliminating the possibility of additional protonation by external H^+ ions.

Destabilization of the Protonated State in the EIVQ Mutant

The E → Q mutation in repeat IV (EIVQ) resulted in a much milder alteration in channel behavior (Fig. 3). This mutation did not prevent blockade by external protons or alter significantly the conductances of either deprotonated and protonated states relative to wild-type channels (Fig. 3 A, and see Fig. 7 B). However, the degree of blockade at pH 8.5 was only 30 ± 2.4% (n = 4) in the EIVQ mutant (Fig. 3 B), compared to 47 ± 1.5% (n = 4) in WT (Fig. 1 B). Compared to the WT channel, the pH^-dependence of the fraction of time spent in the unblocked state was shifted in the acidic direction in the EIVQ mutant (Fig. 3 C), corresponding to a change in pK_a from 8.5 (WT) to 8.2 (EIVQ).

Kinetic analysis illuminated the mechanism of pK_a changes in the EIVQ mutant (Fig. 4). Dwell-time distributions of the unblocked and blocked states of WT channels and the EIVQ mutant were generated from idealized records and fitted with single exponentials. Fig. 4 B shows a comparison of dwell time distributions and the corresponding exponential fits obtained for EIVQ (solid lines) and WT channels (dashed lines) at pH 8.5. It is evident that the mean blocked time was significantly reduced in the EIVQ mutant compared to WT, without a significant change in the mean unblocked time.

Using a conventional procedure to correct for instrumental dead-time and missed events (Colquhoun and Hawkes, 1995), we estimated the dwell time constants for the WT channel and the EIVQ mutant at two different external proton concentrations (Fig. 4 C). At pH 8.5, the corrected dwell time in the deprotonated (unblocked) state was 0.48 ± 0.03 ms (n = 4) for the WT channel and 0.40 ± 0.08 ms (n = 4) for EIVQ, not significantly different (P > 0.05). In contrast, comparison
of the corrected dwell time of the protonated (blocked) state gave values of 0.44 ± 0.1 ms (n = 4) for WT and 0.19 ± 0.03 ms (n = 4) in the E/IQ mutant, a significant reduction (P < 0.001, unpaired t test). Similar results were obtained at pH 7.5 (Fig. 4 C). Thus, the reduction in $K_d$ in the E/IQ mutant was due to an approximately twofold increase in the rate of deprotonation ($\tau_{\text{blocked}}^{-1}$), with no significant change in the protonation rate ($\tau_{\text{unblocked}}^{-1}$). According to analysis of dwell-time distributions in the unblocked state (Fig. 4 C), a 10-fold increase in proton concentration yields a fivefold change in the rates of protonation for both WT channel and E/IQ mutant. Possible explanations of the <10-fold increase in rate include the participation of pH buffer in the proton transfer reaction (see Root and MacKinnon, 1994) or pH-dependent changes in the local surface potential near the mouth of the channel.

We concluded from these results that the protonation site is essentially intact in the E/IQ mutant. While the side-chain carboxylate of the glutamate in repeat IV has no detectable influence on access of protons to the site (lack of effect on blocking rate), it helps to stabilize the bound proton, most likely via through-space electrostatic interaction. The stabilizing influence of E/IQ, revealed by an increase in proton off rate in the E/IQ mutant, can be interpreted in terms of an electrostatic interaction that deepens the energy well for the bound proton (see Root and MacKinnon, 1994) or pH-dependent changes in proton dissociation rate ($\tau_{\text{off}}^{-1}$). According to analysis of dwell-time distributions (Fig. 4 A), a 10-fold increase in proton concentration yields a fivefold change in the rates of protonation for both WT channel and E/IQ mutant. Possible explanations of this <10-fold increase in rate include participation of pH buffer in the proton transfer reaction (see Root and MacKinnon, 1994) or pH-dependent changes in the local surface potential near the mouth of the channel.
to the H state were too brief and infrequent to justify fitting the corresponding bins on the amplitude histogram with a third Gaussian function. To compare relative occupancies of all three conductance states at different pH values, current records were idealized as previously described (Fig. 5 A), and the proportion of channel open time spent at various conductance levels was determined from individual idealized sweeps, then averaged across multiple sweeps and experiments. At pH 8.5, the EIIQ mutant channel spends 5.5 ± 0.6% of its open time at the high conductance level, 83.1 ± 0.5% at the medium level, and 11.4 ± 0.1% at the lowest level (n = 3, Fig. 6 B). The probability of the low conductance state was elevated to 34% at pH 7.5, and reduced to 3.3% at pH 9.75 (Fig. 6 B), whereas occupancy of the medium conductance state showed opposite effects. Thus, the low conductance is likely to correspond to a protonated state, and the medium conductance to a deprotonated state.

In contrast to the M ↔ L equilibrium, the ratio of H and M occupancies remained at ~0.06 over the pH range from 9.75 to 7.5. This indicates that transitions between high and medium states do not involve protonation/deprotonation steps. As an additional test, we compared the behavior of the EIIQ mutant in 2H2O and H2O solutions, but found no significant difference in kinetics of transitions between high and medium conductances (data not shown). This runs contrary to the isotope effect that would be expected if this transition corresponded to a protonation event. The lack of

Each E → Q Mutation Produces a Unique Effect on Proton Block

Each of the P-region glutamates appears to play a distinct role in promoting the intrapore protonation, in line with its asymmetrical contribution to selective interactions with Ca$^{2+}$ and other diveral cations (Kim et al., 1993; Tang et al., 1993; Yang et al., 1993; Ellinor et al., 1995). The E/Q construct showed the sharpest difference in behavior in comparison to native channels. Two findings are particularly interesting: first, E/Q displayed only one current level, whose conductance was in close agreement with that of the protonated state of WT channels (Figs. 2 C and 7), and second, this mutant was completely unresponsive to changes in pH over a range that strongly affected WT channels (Fig. 2 A). These conclusions can be stated quite strongly because the single channel recordings would be capable of resolving even brief and infrequent sojourns at the high conductance level. The combination of results would be difficult to explain if the protonation were to take place at a site separate from E1, which the glutamine substitution had left intact. In such a scenario, mutations might be expected to shift the pH-dependence but not to abolish the deprotonated conductance level in entirety. On the other hand, the ability of the E/Q mutant to mimic and occlude H$^+$-dependent block is exactly the result expected if E1 were directly involved in forming the protonation site: the glutamate substitution for glutamate can be regarded as equivalent to permanently affixing a proton to the carboxylate side chain. This represents compelling evidence that E1 is titrated during the protonation event, and therefore, that the H$^+$ binding site lies within the pore. Accordingly, the well-described dependence of proton block on the permeant ion species (Pietrobon et al., 1989; Prod’hom et al., 1989; Kuo and Hess, 1993; Klockner and Isenberg, 1994) is readily explained without invoking an allosteric mechanism (Pietrobon et al., 1989).

Like E/Q, EIIIQ completely lacked the high conductance level corresponding to the deprotonated state in WT channels. Evidently, glutamine substitutions in motif III and motif I can exert a similar effect on monovalent cation permeation. However, one notable difference is that further protonation is possible for EIIIQ, as indicated by flickery reductions in current to an even lower level (Fig. 2 B). We were unable to study these events in full detail, but it was clear that the reductions in conductance were pH-dependent, albeit over a more acidic range of pH than WT channels. One interpretation that we have considered is that the EIIIQ replacement spares some possibility of protonation of E1, while markedly shifting the pK$_a$ in the acidic direction.

In contrast to E/Q and EIIIQ, the glutamine replacement mutants in motifs II and IV both retained high and low conductance states, although the H$^+$ affinity of EIIQ and EIVQ was reduced relative to WT. The difference between E/IQ and WT was relatively mild, an approximately twofold decrease in proton affinity (Fig. 3 C), suggesting that E/I played only a limited role in stabilizing the bound H$^+$. The change in affinity was accounted for by an increased off-rate of the titratable proton, while the on-rate was hardly affected (Fig. 4). A change in the on-rate would have been expected on the basis of changes in local [H$^+$] if E/I were in ionized form and located on the extracellular side of the pro-
ton binding site. The simplest explanation of our data is that E/V is positioned on the cytoplasmic side of the site. Other lines of evidence provide independent support for this interpretation. Parent and Gopalakrishnan (1995) replaced E/V with less bulky amino acids and found systematic increases in monovalent conductance, as if this residue acted as a final bottleneck for ion permeation. Furthermore, Sather et al. (1994) showed that alanine substitution for E/V has no detectable effect on the on-rate for block by external Cd\(^{2+}\). Thus, E/V appears to be less externally accessible than other P-region glutamates, being located further downstream along the permeation pathway (cf., Tang et al., 1993; Yang et al., 1993). If one presumes that E/V stabilizes protonation by a through-space electrostatic interaction, we calculate that its negative charge must be >10 Å from the titration site (see RESULTS). Notably, the alanine residue at the homologous position of repeat IV of Na\(^+\) channels has also been suggested to lie further along the permeation path than homologous P-region residues in other repeats (Chiamvimonvat et al., 1996), consistent with the overall structural similarity between voltage-gated Ca\(^{2+}\) and Na\(^+\) channels.

The EIIIQ mutation displayed a third conductance level, between the H and L levels, the dominant conducting state of this construct over a wide range of pH. The emergence of this intermediate conductance was quite striking since it was not found in WT or any of the other glutamine substitution mutants. In interpreting the M conductance, a key finding was that while its prevalence relative to the low conductance was pH dependent, its prevalence relative to the high conductance was
We speculate that the H and M states correspond to two distinct configurations of the P-region glutamate side chains, rendered distinguishable by the EIIQ mutation. Since the proton affinity of EIIQ was >10-fold lower than WT, the EII side chain is also likely to be closely associated with the proton binding site, much more so than EIV.

A Model to Explain Distinctive Features of the Ca\(^{2+}\) Channel Protonation Site

Our experiments highlight notable distinctions between H\(^+\) block of Ca\(^{2+}\) channels, Na\(^+\) channels, and cyclic nucleotide-gated (CNG) channels. We found that H\(^+\) block of mutant or wild-type Ca\(^{2+}\) channels involved one protonation reaction at most (see also Prod’hom et al., 1987). In contrast, CNG channels display two independent and identical intrapore titration sites for protons (Root and MacKinnon, 1994). The difference in behavior is particularly intriguing because the CNG channel pore is thought to contain four carboxylate side chains in equivalent positions that form a high-affinity Ca\(^{2+}\) binding site (Root and MacKinnon, 1995), very much like the Ca\(^{2+}\) channel. The most striking difference between Ca\(^{2+}\) channels and Na\(^+\) channels lies in their apparent H\(^+\) affinity. The pK\(_a\) of the protonation site at the extracellular mouth of Na\(^+\) channels is 4.6–4.9 (Woodhull, 1973; Mozhayeva et al., 1981; Zhang and Siegelbaum, 1991; Daumas and Andersen, 1995), close to the pK\(_a\) expected for a single glutamate carboxylate (~4.4). In contrast, the pK\(_a\) of the protonation site within Ca\(^{2+}\) channels (and both of the sites in CNG channels) is more than three log units higher.

Here we propose a model to explain how the four glutamic acid side chains in Ca\(^{2+}\) channels give rise to single protonation site rather than two or more, with a H\(^+\) affinity >10\(^3\)-fold greater than a typical carboxylate. Our results lead us to hypothesize that the protonation site is formed by E.I, acting in conjunction with E.III and to a lesser extent, E.II, while E.IV influences protonation much less directly from a vantage point further along the permeation pathway (Fig. 7 C). In this model, the critical carboxylates take on H\(^+\) ions and are linked together by hydrogen bonds, which minimizes the energetic cost of positioning several negatively charged oxygen groups in close proximity in the absence of divalent cations. Hydrogen bonding networks among multiple carboxylates are quite common in proteins, often exerting a stabilizing force between adjacent sub-units; multiple hydrogen-bonded carboxylates can exhibit a much higher pK\(_a\) than unpaired carboxylates (Sawyer and James, 1982). Hydrogen-bonding between neighboring oxygen groups has been proposed previously for CNG channels, albeit in the form of carboxylic acid-carboxylate pairs (Root and MacKinnon, 1994). In contrast, concerted action of multiple carboxylate side chains is unlikely to occur in Na\(^+\) channels, in which the P-region positions corresponding to residues E.IIIQ are occupied by Asp, Glu, Lys, and Ala (Heinemann et al., 1992). Pairing of the positively charged lysine with one of the acid residues would leave only one carboxylate free as a titratable group, thus accounting for the much lower H\(^+\) affinity of Na\(^+\) channels relative to Ca\(^{2+}\) channels.

We believe that the distinctive characteristics of Ca\(^{2+}\) channel protonation arise from the concerted action of the trio of E.I, E.II, and E.III and that this configuration provides a much more satisfactory account of our observations than arrangements in which E.I and other glutamates act alone or pairwise. For illustrative purposes, we put forward a speculative scenario in Fig. 7 D. In the deprotonated state of the complex, the three carboxylate side chains are held together by a permanently shared H\(^+\) in a three-centered H-bond configuration (Jeffrey and Saenger, 1991). The complex bears a net charge of ~2 and thus offers great attraction for entry of an external proton (indicated by arrow). This electrostatic interaction helps explain the unusually high pK\(_a\) of the Ca\(^{2+}\) channel site. In the deprotonated state, E.I and E.III are likely to be transiently complexed to a monovalent cation or to be tilted out of plane due to electrostatic repulsion between the oxygens, which bear partial negative charge. Once H\(^+\) enters the site, it is shared between E.I and E.III, allowing these side chains to become coplanar; the symmetry of the resulting carboxyl–carboxyl complex contributes further to the high pK\(_a\). The reduction in negative charge due to protonation would be expected to decrease the rate of monovalent cation flux, thus producing a subconductance state.

How might this model account for the E.IQ and E.IIQ phenotypes? Substitution of an -NH\(_2\) for an -O on either E.I and E.III would neutralize the side chain, acting in lieu of a titratable H\(^+\), resulting in formation of an N–H–O hydrogen bond or formation of alternative carboxyl–carboxylate pairs that were not present in the WT. We suggest that, for either E.I or E.III, charge neutralization would mimic the effect of protonation in driving the channel out of the high conductance state. On the other hand, we speculate that E.I and E.III might be expected to differ in whether the glutamine replace-
ment abolished all possibility of protonation, depending on geometrical position of these side chains in the channel pore or their chemical interaction with EII side chain or other neighboring residues. It is likely that E/F is involved in additional protonation in EIQQ mutant, leading to the expectation that simultaneous glutamine substitution for both E/F and EIII would produce extremely small unitary currents, like those seen with the protonated state of EIQQ. Indeed, oocytes expressing the EIQ-Q-EIQQ double mutant have shown small Ba2+ currents in whole-cell recordings and no clear unitary K+ currents in preliminary cell-attached recordings. This seems consistent with the hypothesis, but we cannot yet exclude the possibility that expression of the EIQQ construct is simply inefficient.

Possible Insights into the Mechanism of Ca2+ Permeation

H+ interactions provided a novel perspective on the behavior of the pore glutamates, useful in understanding their participation in Ca2+ selectivity and permeation. The proposed apposition of P-region glutamates I, II, and III is of great interest, not only as a possible high-affinity protonation site, but also because it represents an array of oxygen groups not unlike those found in high-affinity Ca2+ binding sites of known three-dimensional structure (Falke et al., 1994). There are clues that arrival of a divalent cation at the glutamate locus might cause some rearrangement in its configuration. For example, while EIV has only mild influence on H+ block in the absence of Ca2+, mutations at this position affect Ca2+ and Cd2+ block to a far greater extent than could be explained by a through-space electrostatic interaction (Kim et al., 1993; Tang et al., 1993; Yang et al., 1995; Ellinor et al., 1995). This disparity would make sense if Ca2+ interaction with the EIFE/EIII complex allowed the EIV carboxylate to swing into position to provide additional coordination for the divalent cation. As discussed above, an additional hint of conformational freedom in the P-region glutamates was provided by the behavior of the EIQ mutant, which displayed pH-independent transitions between high and medium conductances. The proposed rearrangements provide examples of what might be possible when the pore accommodates multiple Ca2+ ions. Conformational flexibility in the glutamate locus may be particularly important as a mechanism for mediating ion–ion interactions, thereby allowing the pore to support high rates of divalent cation transfer (Tsien et al., 1987; Armstrong and Neyton, 1992; Kuo and Hess, 1993; Yang et al., 1993).

Physiological Implications of Proton Regulation of Ca2+ Influx

These results provide a molecular basis for an important regulatory function of extracellular pH: the control of ion flux through open Ca2+ channels. The steeply pH-dependent reduction of unitary current will help decrease the overall Ca2+ influx, together with reduced channel open probability (Prod’hom et al., 1987; Krafte and Kass, 1988; Klöckner and Isenberg, 1994). Our experiments provide a simple and satisfying explanation for the antagonism between H+ and Ca2+. At physiological [Ca2+]o, competition for pore glutamates will strongly influence the pKs for protons, thus explaining why changes in external pH in the vicinity of pH 7 produce such marked effects on voltage-gated Ca2+ current (Krafte and Kass, 1988; Pietrobon et al., 1989; Klockner and Isenberg, 1994) and K+-induced Ca2+ entry (Ou-Yang et al., 1994). The inhibition of Ca2+ entry by H+ will exert a substantial effect in the modulation of cell excitability during vigorous neuronal activity (Chesler and Kaila, 1992) and the promotion of cell survival during epileptic seizures and short-term cerebral or cardiac ischemia (Katz, 1992; Siesjo et al., 1993).

Because the P-region glutamates are perfectly conserved in all known α1 subunits of voltage-gated Ca2+ channels, pronounced pH-sensitivity is likely to be a universal characteristic of this family of membrane proteins. This is in contrast to NMDA receptor channels, whose regulation by pHo (Traynelis and Cull-Candy, 1991) is markedly dependent on a specific RNA splice variation, in exon 5 (Traynelis et al., 1995). Unlike voltage-gated Ca2+ channels, NMDA receptors respond to external acidification not by a reduction in open channel current but strictly by decreased likelihood of channel opening (Traynelis and Cull-Candy, 1991). Thus, the two major pathways for synaptically driven Ca2+ entry show similar overall responsiveness to pHo, but by fundamentally different molecular mechanisms.

We thank R. Agin for technical assistance, T. Tanabe (Yale University) for α1 and α2 subunit cDNAs, J. Yang (University of California, San Francisco) and P.T. Ellinor (Stanford University) for mutant α1 and cDNAs, V. Flockerzi and F. Hofmann (Institut für Pharmakologie und Toxikologie, Technische Universität, München, Germany) for β3 subunit cDNA, R. Aldrich, K. Deissroth, G. Liu, H. Bito, T. Schwarz, and J.-F. Zhang for comments on the manuscript, W.A. Sather for instruction on patch-clamp methods, and J.J. Falke, D. Heschlag, R.Y. Tsien, J.W. Stocker, and W. Weis for advice on chemical structures.

This work was funded by research grants from National Institutes of Health, the Mathers Foundation, and the Silvio Conte-NIMH Center for Neuroscience Research at Stanford and training grants from the American Heart Association (California Affiliate (X.-H. Chen) and NIH (I. Bezprozvannya). We are grateful to Jing Li and Svetlana Bezprozvannya for support.
