K⁺ Occupancy of the N-methyl-D-aspartate Receptor Channel Probed by Mg²⁺ Block

YONGLING ZHU and ANTHONY AUERBACH

From the Department of Physiology and Biophysics, State University of New York at Buffalo, Buffalo, New York 14214

ABSTRACT The single-channel kinetics of extracellular Mg²⁺ block was used to probe K⁺ binding sites in the permeation pathway of rat recombinant NR1/NR2B NMDA receptor channels. K⁺ binds to three sites: two that are external and one that is internal to the site of Mg²⁺ block. The internal site is ~0.84 through the electric field from the extracellular surface. The equilibrium dissociation constant for this site for K⁺ is 304 mM at 0 mV and with Mg²⁺ in the pore. The occupancy of any one of the three sites by K⁺ effectively prevents the association of extracellular Mg²⁺. Occupancy of the internal site also prevents Mg²⁺ permeation and increases (by approximately sevenfold) the rate constant for Mg²⁺ dissociation back to the extracellular solution. Under physiological intracellular ionic conditions and at ~60 mV, there is ~1,400-fold apparent decrease in the affinity of the channel for extracellular Mg²⁺ and ~2-fold enhancement of the apparent voltage dependence of Mg²⁺ block caused by the voltage dependence of K⁺ occupancy of the external and internal sites.

KEY WORDS: ion binding sites • magnesium • channel block • permeation • selectivity

INTRODUCTION

The N-methyl-D-aspartate receptor (NMDAR) channel is permeable to Na⁺, K⁺, and Ca²⁺, and is blocked by Zn²⁺ and Mg²⁺. Numerous studies have addressed the position and nature of binding sites for Na⁺, Ca²⁺, Zn²⁺, and Mg²⁺ in the NMDAR ion permeation pathway (Burnashev et al., 1992; Mori et al., 1992; Premkumar and Auerbach, 1996; Sharma and Stevens, 1996a,b; Wollmuth et al., 1998; Antonov and Johnson, 1999; Fayyazuddin et al., 2000; see Zhu and Auerbach, 2001, in this issue). However, interactions between K⁺ and the NMDAR channel have not been examined in detail, even though this ion is highly permeable and is normally present in the intracellular milieu at a high concentration. In this paper, we present information regarding the location and affinity of K⁺ binding sites in recombinant NR1-NR2A NMDARs, inferred from the kinetics of Mg²⁺ block as a function of the extracellular and intracellular concentrations of K⁺.

Previous studies have demonstrated that Na⁺ binds to two sites that are external to the Mg²⁺ binding site and that are accessible from both the intra- and extracellular solutions. Occupancy of these sites by Na⁺ prevents the movement of extracellular Mg²⁺ between the extracellular compartment and the pore (i.e., blocks the association and “locks in” Mg²⁺). We find that in addition to interacting with these external sites, K⁺ binds to a site that is near the intracellular entrance of the permeation pathway. Occupancy of this internal site by K⁺ reduces the rate constants for extracellular Mg²⁺ association and permeation, and increases the rate constant of Mg²⁺ dissociation back to the extracellular solution. Under physiological conditions, the interactions between K⁺ and Mg²⁺ in the NMDA pore affect the affinity and voltage dependence of Mg²⁺ blockade.

MATERIALS AND METHODS

Wild-type rat cRNAs for the rat NR1 and NR2A subunits were expressed in Xenopus oocytes. Single-channel currents were recorded from outside-out patches. A detailed description of the molecular biology, expression protocols, electrophysiology, solutions, signal processing, kinetic analysis, and fitting procedures is given in Zhu and Auerbach (2001, in this issue).

RESULTS

The results are presented in four sections: first, the effects of intracellular K⁺ ([K⁺]ᵢ) on Mg²⁺ dissociation and permeation; second, the effects of [K⁺]ᵢ on Mg²⁺ association; third, the effects of extracellular K⁺ ([K⁺]ₑ) on Mg²⁺ association; and fourth, the effects of [K⁺]ₑ on Mg²⁺ dissociation and permeation.

Intracellular K⁺ Increases the Mg²⁺ Dissociation Rate Constant and Decreases the Mg²⁺ Permeation Rate Constant

Increasing intracellular [K⁺] shortens the duration of the gaps arising from Mg²⁺ block (Fig. 1A); i.e., Mg²⁺ is released from the NMDAR pore more rapidly when [K⁺]ᵢ is elevated. The apparent Mg²⁺ release rate (kₒᵢ)
The Effects of Intracellular $[K^+]_i$ on the Apparent Rates of Mg$^{2+}$ Dissociation and Permeation

$[K^+]_i$ is the intracellular $K^+$ concentration, $k^0_{\text{Mg}}$ is the Mg$^{2+}$ dissociation rate constant with no membrane potential, $\varepsilon$ is the electrical distance from the Mg$^{2+}$ binding site to the peak of the dissociation barrier, and $k^0_{\text{Mg},\text{in}}$ is the Mg$^{2+}$ permeation rate constant with no membrane potential (see Fig. 6 in companion article Zhu and Auerbach, 2001, in this issue). The results were obtained by fitting the experimental results of Fig. 1 B using Eq. 1. Mg$^{2+}$ dissociates more rapidly, and permeates more slowly, in high $[K^+]_i$.

The result of fitting the experimental $k_{\text{off}}$ values using Eq. 1 are shown in Table I. At 0 mV, $k_{\text{off}}$ is larger and $k_{\text{off}}$ in 150 mM compared with 5 mM $[K^+]_i$; i.e., elevating intracellular $[K^+]_i$ enhances Mg$^{2+}$ dissociation back to the extracellular space, but reduces Mg$^{2+}$ permeation to the intracellular space.

The NMDAR channel has external binding sites that are able to bind Cs$^+$ and Na$^+$ (Antonov and Johnson, 1999). The effects of $[K^+]_i$ on the Mg$^{2+}$ dissociation and permeation rate constants cannot, however, be explained by $K^+$ occupancy of these external sites because intracellular $K^+$ does not have access to the external sites when Mg$^{2+}$ blocks the channel. Therefore, intracellular $K^+$ must be interacting with regions of the protein that are internal to the Mg$^{2+}$ binding site. We assume the reduction in $k_{\text{off}}$ with increasing $[K^+]_i$ occurs because the occupancy of this internal site by $K^+$ blocks the pathway for Mg$^{2+}$ permeation into the intracellular compartment. Moreover, we speculate that the enhancement of $k_{\text{off}}$ with increasing $[K^+]_i$ may be caused by an electrostatic repulsion between the two ions.

To further quantify the effects of $[K^+]_i$ on Mg$^{2+}$ dissociation, we used a model having one external Na$^+$ site and one internal K$^+$ site. The model assumes that Mg$^{2+}$ cannot dissociate if the external site is occupied, and that Mg$^{2+}$ dissociates at two different rate constants depending on whether or not the internal site is occupied. Accordingly, the apparent dissociation rate constant ($k^V_{\text{Mg}}$) is described by:

$$k^V_{\text{Mg}} = k^0_{\text{Mg}} e^{\frac{2eV}{k_BT}} + k_{\text{off}}^0,$$

where $V$ is the membrane potential, the superscript 0 indicates the salient rate constant at 0 mV, $k_0$ is Boltzmann’s constant, $T$ is the absolute temperature (under our conditions, $k_BT = 25.3$ mV), and $\varepsilon$ is the fractional electrical distance from the Mg$^{2+}$ binding site to the top of the dissociation energy barrier. Results regarding Na$^+$ interactions with Mg$^{2+}$ indicate that $k_{\text{off}}$ is essentially voltage-independent (see Zhu and Auerbach, 2001, in this issue). Therefore, in Eq. 1, the fractional electrical distance from the Mg$^{2+}$ binding site to the top of the permeation barrier was assumed to be zero.

The $[K^+]_i$ is the intracellular $K^+$ concentration, $k^2_{\text{Mg}}$ is the Mg$^{2+}$ dissociation rate constant with no membrane potential, $\varepsilon$ is the electrical distance from the Mg$^{2+}$ binding site to the peak of the dissociation barrier, and $k^0_{\text{Mg},\text{in}}$ is the Mg$^{2+}$ permeation rate constant with no membrane potential (see Fig. 6 in companion article Zhu and Auerbach, 2001, in this issue). The results were obtained by fitting the experimental results of Fig. 1 B using Eq. 1. Mg$^{2+}$ dissociates more rapidly, and permeates more slowly, in high $[K^+]_i$.

Intracellular K\(^+\) Reduces the Mg\(^{2+}\) Association Rate Constant

In this section, we address the Mg\(^{2+}\) association rate constant as a function of intracellular [K\(^+\)]. Fig. 2 A shows that the open channel lifetimes are longer (i.e., the Mg\(^{2+}\) association rate constant is slower; Fig. 2 B) when [K\(^+\)]\(_{\text{in}}\) is elevated. We first considered whether the apparent reduction in the Mg\(^{2+}\) association rate constant is caused exclusively by the binding of intracellular K\(^+\) to the external monovalent cation sites. We made the simplifying assumptions that the two external sites are independent and identical, and that the occupancy of these sites by extracellular Na\(^+\) is not voltage-dependent. Three sets of data, obtained at different [K\(^+\)]\(_{\text{in}}\) (25, 50, and 100 mM) and at 100 mM [Na\(^+\)]\(_{\text{ex}}\), were fitted simultaneously by:

\[
k_{V}^{\text{off},Mg} = \kappa_{pMg}^{0} \left(1 + \frac{[K^{+}]_{\text{in}}}{J_{A_{\text{Na},\text{internal}}}}\right)^{-1},
\]

where \(\kappa_{pMg}^{0}\) is the intrinsic rate constant for Mg\(^{2+}\) permeation (with the internal site empty and no membrane potential), and \(k_{V}^{\text{off},Mg}\) is the net Mg\(^{2+}\) permeation rate constant, which is a function of only two experimental variables, [K\(^+\)]\(_{\text{in}}\) and V.

The experimental values of \(k_{V}^{\text{off}}\) were fitted by the sum of Eqs. 2 and 3, which has four free parameters (Table II). Fig. 1 C shows that the predicted curves match the experimental data, indicating that a single internal K\(^+\) binding site is sufficient to explain the effects of [K\(^+\)]\(_{\text{in}}\) on Mg\(^{2+}\) release from the pore. The Mg\(^{2+}\) dissociation rate constant is approximately seven times greater when there is a K\(^+\) at the internal site compared with when this site is empty. The affinity of the internal site for K\(^+\) when there is a Mg\(^{2+}\) in the pore is low, perhaps because of electrostatic repulsion between the ions. The internal K\(^+\) binding site is ~84\% through the electric field from the extracellular surface, and is ~24\% deeper in the electric field than the Mg\(^{2+}\) binding site.

The experimentally observed Mg\(^{2+}\) off rates measured at 150 mM and 5 mM [K\(^+\)]\(_{\text{in}}\) and between –10 and –60 mV (Fig. 1 C) were simultaneously fitted by the sum of Eqs. 2 and 3. To restrict the number of free parameters, three terms were fixed at their previous estimates \(\kappa_{pMg}^{0} = 624\) s\(^{-1}\), \(e = 0.36\), and \(J_{A_{\text{Na},\text{ex}}} = 89\) mM). The estimate of \(k_{t,Mg}^{0}\) is similar to that obtained from experiments in different [Na\(^+\)] (see Zhu and Auerbach, 2001, in this issue).
To quantify the observations, we used a scheme that had four ion binding sites: two external sites that bind Na\(^+\) or K\(^+\); one intermediate site that is selective for Mg\(^{2+}\); and one internal site that is selective for K\(^+\). For simplicity, we assumed that occupancy of any one of the three monovalent cation binding sites completely prevents the association of extracellular Mg\(^{2+}\). (Although the results given in Table II suggest that intracellular K\(^+\) can bind to the internal site when the channel is blocked by Mg\(^{2+}\), in the following analysis, we made the simplifying assumption that Mg\(^{2+}\) association is effectively eliminated when K\(^+\) occupies the internal site.) A 12-state model is required to account for the effects of intracellular K\(^+\) and extracellular Na\(^+\) on the Mg\(^{2+}\) association rate constant, with six external site configurations (two Na\(^+\), two K\(^+\), one Na\(^+\) and one K\(^+\), one Na\(^+\), one K\(^+\), and empty) and two internal site configurations (one K\(^+\) and empty).

We assume that the apparent association rate constant for Mg\(^{2+}\) is a function of the probability of all three of the monovalent cation sites being empty:

\[
k_{V\text{-Mg}} = k_{V\text{-Mg}}(P_{\text{external}}^{e})(P_{\text{internal}}^{e}),
\]

where \(P_{\text{external}}^{e}\) and \(P_{\text{internal}}^{e}\) are the probabilities of the external sites and the internal site being empty. The apparent Mg\(^{2+}\) association rate constant is related to the experimental variables \([\text{Na}^+]_{\text{ex}}\), \([\text{K}^+]_{\text{in}}\), and \(V\) by:

\[
k_{V\text{-Mg}} = \frac{k_0^{V\text{-Mg}}}{2} e^{-\frac{\Delta V}{k_B T}} \left(1 + \frac{[\text{Na}^+]_{\text{ex}}}{K_{\text{Na}_{\text{ex}}}} + \frac{[\text{K}^+]_{\text{in}}}{K_{\text{K}_{\text{in}}} e^{\frac{\Delta V}{k_B T}}}ight)^{-1} \left(1 + \frac{[\text{K}^+]_{\text{in}}}{K_{\text{K}_{\text{in}}} e^{\frac{\Delta V}{k_B T}}}ight)^{-1}.
\]

The first term in parentheses is the inhibition of Mg\(^{2+}\) association because of Na\(^+\) and K\(^+\) occupancy of the two external sites and the second term in parentheses is the inhibition because of K\(^+\) occupancy of the single internal site. \(K_{\text{Na}_{\text{ex}}}^{0}\) and \(K_{\text{K}_{\text{in}}}^{0}\) are the only free parameters. The predicted curves match the experimental data. We conclude that a model having two external monovalent cation-binding sites and one internal K\(^+\)-selective site accounts for the effects of intracellular \([\text{K}^+]_{\text{in}}\) on Mg\(^{2+}\) association. The parameters for the best fit are shown in Table III.

**Extracellular K\(^+\) Decreases the Mg\(^{2+}\) Association Rate Constant**

We next investigated the effects of extracellular K\(^+\) on the Mg\(^{2+}\) association rate constant. Fig. 3 A illustrates single-channel currents recorded at two different extracellular K\(^+\) concentrations ([K\(^+\)]\(_{\text{ex}}\) 25 and 150 mM) in the presence of 100 mM intracellular Na\(^+\). The channel open lifetime is longer at the higher [K\(^+\)]\(_{\text{ex}}\) indicating that the Mg\(^{2+}\) association rate constant decreases with an increase in [K\(^+\)]\(_{\text{ex}}\). We again used the two-external, one-internal site model to quantify the results. We assumed that all three sites can bind extracellular K\(^+\), and that occupancy of any one of these sites by K\(^+\) effectively eliminates Mg\(^{2+}\) association. We also assumed that that Na\(^+\) does not bind to the internal site.

![Image of the figure 2](image-url)
For this model, we used an expression that relates the apparent association rate constant \( k_{\text{V,Mg}}^{\text{V}} \) to \([\text{K}^+]_{\text{ex}}, [\text{Na}^+]_{\text{in}}\), and \( V \):

\[
k_{\text{V,Mg}}^{\text{V}} = \frac{\kappa_{\text{V,Mg}} c_{\text{Mg}}^{1/2} [\text{K}^+]_{\text{ex}}^{1/2} \left(1 + \frac{[\text{Na}^+]_{\text{in}}}{K_{\text{Na}}^{\text{Na}} c_{\text{Na}}^{1/2}}\right)^{1/2} \left(1 + \frac{[\text{K}^+]_{\text{ex}}}{K_{\text{K}}^{\text{K}} c_{\text{K}}^{1/2}}\right)}{\kappa_{\text{V,Mg}}^{\text{V}} c_{\text{Mg}}^{1/2} \left(1 + \frac{[\text{Na}^+]_{\text{in}}}{K_{\text{Na}}^{\text{Na}} c_{\text{Na}}^{1/2}}\right)^{1/2} \left(1 + \frac{[\text{K}^+]_{\text{ex}}}{K_{\text{K}}^{\text{K}} c_{\text{K}}^{1/2}}\right)}.
\]

(6)

Fig. 3 D shows experimental \( k_{\text{V,Mg}}^{\text{V}} \) values obtained at three different \([\text{K}^+]_{\text{ex}}\) as a function of the membrane potential, fitted simultaneously by Eq. 6. The fitting results are given in Table IV. The fitted curves provide a good description of the experimental data, indicating that a model with two external sites that can bind either \( \text{Na}^+ \) or \( \text{K}^+ \), and with one internal site that is \( \text{K}^+ \)-selective, accounts for the effects of extracellular \( \text{Na}^+ \) and \( \text{K}^+ \) on the \( \text{Mg}^{2+} \) association rate constant.

In the absence of a membrane potential, the internal site has an extremely low apparent affinity for extracellular \( \text{K}^+ \). To evaluate the significance of extracellular \( \text{K}^+ \) occupancy of the internal site with regard to \( \text{Mg}^{2+} \) association, we fitted the same experimental data using a model that allowed \( \text{K}^+ \) to bind only to the external sites. The equations for this fit were the same as were used to describe the effects of extracellular \( \text{Na}^+ \) on \( \text{Mg}^{2+} \) association (see Zhu and Auerbach, 2001, in this issue). The results show that the fit using this scheme (Fig. 3 C; Model Selection Criterion = 4.6) is significantly worse than the fit by Eq. 6 (Fig. 3 D; Model Selection Criterion = 5.4). Without the incorporation of an

![Figure 3](image-url)

**Figure 3.** Effects of extracellular \( \text{K}^+ \) on the \( \text{Mg}^{2+} \) association rate constant. (A) Single-channel currents at different extracellular \( \text{K}^+ \) concentrations (2 \( \mu \text{M} \text{Mg}^{2+} \) in the extracellular solution; the intracellular solution contained 150 mM \( \text{Na}^+ \); \( V = -100 \text{ mV} \)). (B) The inverse of open channel lifetime plotted as a function of \( \text{Mg}^{2+} \) concentration. The decreased slope with increasing \([\text{K}^+]_{\text{ex}}\) indicates that extracellular \( \text{K}^+ \) reduces the \( \text{Mg}^{2+} \) association rate constant. (C) Fits of the experimental \( \text{Mg}^{2+} \) association rate constants using a model where extracellular \( \text{K}^+ \) binds only to the two external sites. (see Eq. 3 from Zhu and Auerbach, 2001, in this issue; Model Selection Criterion = 4.6). (D) Fits of the experimental \( \text{Mg}^{2+} \) association rate constants using a model where extracellular \( \text{K}^+ \) binds to two external sites and one internal site (Eq. 6; Model Selection Criterion = 5.4). Parameters for the best fit are shown in Table IV. The model with two external and one internal binding site for extracellular \( \text{K}^+ \) is superior. The SDs are all smaller than the symbol.

The values were obtained by fitting Eq. 5 to the experimental \( \text{Mg}^{2+} \) association rates obtained at different \([\text{K}^+]_{\text{ex}}\) and voltages (Fig. 2 D). The electrical distances (\( \alpha = 0.83, \beta = 0.16, \) and \( \delta = 0.27 \)) and the apparent dissociation constant of the external site for extracellular \( \text{Na}^+ \) (\( K_{\text{Na}}^{\text{Na}} = 42 \text{ mM} \)) were fixed at their previously determined values (see Zhu and Auerbach, 2001, in this issue). The estimate of the \( \text{Mg}^{2+} \) association rate constant in pure water is close to that obtained from experiments in different \([\text{Na}^+]_{\text{ex}}\) (see Zhu and Auerbach, 2001, in this issue).
internal K\textsuperscript+ binding site, the predicted curves deviate from the experimental results because of an overestimation of the voltage dependence of k\textsubscript{V}Mg. The small apparent voltage dependence of k\textsubscript{V}Mg can be attributed to voltage-dependent binding of extracellular K\textsuperscript+ to the internal sites, which are deep within the electric field. Hyperpolarization increases Mg\textsuperscript{2+} association, but also enhances the occupancy of the internal site by extracellular K\textsuperscript+\textsubscript{ex}, which in turn serves to reduce the Mg\textsuperscript{2+} association rate constant. Thus, the results support the conclusion that extracellular K\textsuperscript+\textsubscript{ex} binds to both the external sites and the internal site.

**Extracellular K\textsuperscript+ Reduces the Mg\textsuperscript{2+} Dissociation Rate Constant but Increases the Mg\textsuperscript{2+} Permeation Rate Constant**

Extracellular K\textsuperscript+ and Na\textsuperscript+ have different effects on the kinetics of Mg\textsuperscript{2+} unbinding. [Na\textsuperscript+]\textsubscript{ex} reduces the rate of Mg\textsuperscript{2+} release from the channel. In contrast, [K\textsuperscript+]\textsubscript{ex} shortens the gaps in the single-channel record that reflect sojourns of Mg\textsuperscript{2+} in the channel (Fig. 4 A), indicating that extracellular K\textsuperscript+ increases the rate of Mg\textsuperscript{2+} release. In addition, the blocking gaps are longer-lived in equivalent concentrations of Na\textsuperscript+ versus K\textsuperscript+, which further highlights the distinct effects of these two cations.

Fig. 4 B shows k\textsubscript{off} measured at different [K\textsuperscript+]\textsubscript{ex} over a wide range of membrane potentials. (In these experiments, there was no extracellular [Na\textsuperscript+]\textsubscript{ex}). k\textsubscript{off} increases with increasing [K\textsuperscript+]\textsubscript{ex} between −100 and −140 mV. However, the difference between k\textsubscript{off} in 25 vs. 150 mM [K\textsuperscript+]\textsubscript{ex} becomes smaller as the membrane is depolarized, until it disappears entirely at about −80 mV.

We assume that extracellular K\textsuperscript+ binding to the external sites is voltage-independent. The apparent Mg\textsuperscript{2+} dissociation and permeation rate constants were ob-

</table>

The values were obtained by fitting Eq. 6 to the experimental Mg\textsuperscript{2+} association rates obtained at different intracellular [K\textsuperscript+] and voltages (Fig. 3 C). To restrict the number of free parameters, the three electrical distances (δ = 0.27, α = 0.83, and β = 0.16) and the dissociation constant of the external site for intracellular Na\textsuperscript+ (K\textsubscript{KdNa} = 5 mM) were fixed at their previous estimates (see Zhu and Auerbach, 2001, in this issue). At −120 mV, K\textsubscript{K,internal} = 300 mM.
First, we assumed that only one extracellular K$^+$ binds when the pore is blocked by Mg$^{2+}$. Thus, the observed Mg$^{2+}$ permeation rate constant ($k_{\text{pMg}}^V$) is the weighted average of only two components, the permeation rate constant without ($k_{\text{0pMg}}^V$) and with ($k_{\text{1pMg}}^V$) a bound K$^+$:

$$k_{\text{pMg}}^V = k_{\text{0pMg}}^V e^{-\frac{23\Delta V}{k_BT}} \left(1 + \frac{[\text{K}^+]_{\text{ex}}}{K_{\text{ex}}}ight)^{-1} + k_{\text{1pMg}}^V e^{-\frac{23\Delta V}{k_BT}} \frac{K_{\text{ex}}}{[\text{K}^+]_{\text{ex}}} \left(1 + \frac{[\text{K}^+]_{\text{ex}}}{K_{\text{ex}}}ight)^{-1}. \quad (8)$$

Note that we have assumed that the voltage dependence of Mg$^{2+}$ permeation (given by the electrical distance parameter, $\lambda$) is the same regardless of the occupancy status of the external site. The observed net Mg$^{2+}$ release rate ($k_{\text{off}}^V$) as a function of [K$^+$]$_{\text{ex}}$ and V was fitted by the sum of Eq. 7 (with $n = 1$) and Eq. 8. The best-fit parameters (Table VI) indicate that, with this scheme, the Mg$^{2+}$ permeation rate constant is approximately three times greater when there is a K$^+$ at the external site compared with that when this site is empty.

The second model assumed that extracellular K$^+$ occupies either of two external sites, but that the occupancy of only one influences Mg$^{2+}$ permeation:

$$k_{\text{pMg}}^V = k_{\text{0pMg}}^V e^{-\frac{23\Delta V}{k_BT}} \left(1 + \frac{[\text{K}^+]_{\text{ex}}}{K_{\text{ex}}}ight)^{-2} + k_{\text{1pMg}}^V e^{-\frac{23\Delta V}{k_BT}} \left(\frac{[\text{K}^+]_{\text{ex}}}{K_{\text{ex}}} \left(1 + \frac{[\text{K}^+]_{\text{ex}}}{K_{\text{ex}}}ight)^{-1} + \left(\frac{[\text{K}^+]_{\text{ex}}}{K_{\text{ex}}}\right)^{-2}\right). \quad (9)$$

The observed Mg$^{2+}$ release rate ($k_{\text{off}}^V$) as a function of [K$^+$]$_{\text{ex}}$ and V was again fitted simultaneously by the sum of Eqs. 7 (with $n = 2$) and 9. The best-fit parameters (Table VI) indicate that, with this scheme, the Mg$^{2+}$ permeation rate constant again is more than two times greater when there is a K$^+$ at the external site compared with that when this site is empty.

The quantitative analysis of the effects of [K$^+$]$_{\text{ex}}$ on Mg$^{2+}$ permeation is more complex because this process could be differentially affected in the case of zero, one, or two K$^+$ bound to the external sites. We use three different models to fit the data.
Finally, we attempted to use a model where the occupancy of two external sites influences both dissociation and permeation, so that the observed Mg\(^{2+}\) permeation rate constant is a weighted average of three components:

\[
\begin{align*}
  k^0_{pMg} &= k^0_{pMg} e^{-\frac{z_1^{Na} F V}{k_BT}} \left( 1 + \frac{[K^+]_{ex}}{K_{d,Kex}} \right)^2 \left( 1 + \frac{K_{d,Kex}}{[K^+]_{ex}} \right)^{-1} \\
  + k_{1,pMg} e^{-\frac{z_1^{Na} F V}{k_BT}} \left( 1 + \frac{K_{d,Kex}}{[K^+]_{ex}} \right)^{-1} \left( 1 + \frac{K_{d,Kex}}{[K^+]_{ex}} \right)^{-1} \\
  + k_{2,pMg} e^{-\frac{z_1^{Na} F V}{k_BT}} \left( 1 + \frac{K_{d,Kex}}{[K^+]_{ex}} \right)^{-2}
\end{align*}
\]

The fit by the sum of Eq. 7 (with \(n = 2\)) and Eq. 10 to the observed Mg\(^{2+}\) “off” rates would not converge. There was a large SD in the estimated value of \(k^0_{2,pMg}\) even after constraining \(k^0_{2,pMg}\).

In summary, the occupancy of the external site(s) by K\(^+\) increases the Mg\(^{2+}\) permeation rate constant by about a factor of three. The analysis does not allow us to distinguish if there are one or two such sites, and, in the case of two sites, if double occupancy alters Mg\(^{2+}\) permeation to a different extent than single occupancy.

**A Qualitative Assessment of the Affinity and Selectivity of the Internal Site**

In contrast to the external sites, we hypothesize that the internal site specifically binds K\(^+\). The low relative affinity of the internal site for intracellular Na\(^+\) versus K\(^+\) is immediately apparent in Fig. 5, which shows the voltage dependence of \(k_{-Mg}\). At \(-140\) mV, \(k_{-Mg}\) is the same in 100 and 5 mM [Na\(^+\)]\(_{in}\) (Fig. 5 A). This is because the occupancy of intracellular Na\(^+\) is either the external or internal sites at this hyperpolarized potential. The external site has an apparent dissociation constant of 552 mM for intracellular Na\(^+\) at \(-140\) mV; see Zhu and Auerbach, 2001, in this issue) However, at \(-80\) mV, \(k_{-Mg}\) is 1.6 times smaller in 100 mM vs. 5 mM [Na\(^+\)]\(_{in}\). This is because, upon depolarization, intracellular Na\(^+\) increasingly occupies the external sites (after crossing the entire electric field) and increasingly inhibits Mg\(^{2+}\) association. The significantly higher voltage dependence in high intracellular Na\(^+\) is evidence that intracellular Na\(^+\) binds mainly to the external sites, and that the affinity of the internal site for Na\(^+\) is so low that it can be ignored.

In contrast, the internal site has a relatively high affinity for K\(^+\). Fig. 5 B shows that [K\(^+\)]\(_{in}\) inhibits Mg\(^{2+}\) association at hyperpolarized potentials, and that this inhibition does not show a strong voltage dependence. This is a reflection of the weak voltage dependence of the occupancy of the internal site by intracellular K\(^+\). (The internal site apparent affinity for intracellular K\(^+\) increases only from 25 mM at 0 mV to 55 mM at \(-140\) mV). We conclude that intracellular Na\(^+\) binds mainly to the external sites, whereas intracellular K\(^+\) binds to a significant extent to both the internal and the external sites.

Fig. 5 also illustrates that the internal site also selects for K\(^+\) over Na\(^+\) when these ions originate from the extracellular compartment. The inhibition of \(k_{+Mg}\) by extracellular Na\(^+\) shows only a slight voltage dependence (Fig. 5 C), whereas the inhibition by extracellular K\(^+\) shows a strong voltage dependence (Fig. 5 D). This is consistent with the interpretation that extracellular Na\(^+\) binds mainly to the external sites, whereas extracellular K\(^+\) binds both to the external sites as well as to the internal site, which lies deep in the electric field.

**DISCUSSION**

**Ion Binding Sites in the NMDAR Permeation Pathway**

Fig. 6 shows a fanciful representation of the ion binding sites in the NMDAR pore, motivated by the close

**Figure 5.** The distinct effects of Na\(^+\) and K\(^+\) on the voltage dependence of Mg\(^{2+}\) association reflect the locations of the monovalent cation-binding sites. (A) The inhibition of \(k_{-Mg}\) by [Na\(^+\)]\(_{in}\) is voltage-dependent because intracellular Na\(^+\) must cross the entire electric field to occupy the external sites. (B) The inhibition of \(k_{-Mg}\) by [K\(^+\)]\(_{in}\) is only weakly voltage-dependent between \(-140\) and \(-80\) mV because, in this range, intracellular K\(^+\) blocks Mg\(^{2+}\) association via the occupancy of the internal site. The large inhibition at \(-55\) mV arises from K\(^+\) occupancy of the external site. (C) The inhibition of \(k_{+Mg}\) by [Na\(^+\)]\(_{ex}\) is not voltage-dependent because extracellular Na\(^+\) does not have to enter the entire electric field to occupy the external sites. (D) The inhibition of \(k_{+Mg}\) by [K\(^+\)]\(_{ex}\) is voltage-dependent because extracellular K\(^+\) can cross the entire electric field to occupy the internal site. Its occupancy of the external sites is significant, but voltage-independent.

and cation-selective glutamate receptor channels. When the channel is free of Mg\(^{2+}\), Na\(^{+}\), and K\(^{+}\) interact with two sites that are located in the external portion of the permeation pathway. Either both monovalent cation sites are located outside the electric field, or one is outside and the other is about midway through the electric field (see Zhu and Auerbach, 2001, in this issue), perhaps in a central cavity. K\(^{+}\) also lingers at an additional site that is in the internal portion of the permeation pathway. As a fraction of the electric field (from the extracellular solution), the Mg\(^{2+}\) site is at \(\sim 0.60\), and the internal, K\(^{+}\)-selective site is at \(\sim 0.84\).

Although we can estimate the locations of the ion-binding sites in terms of their electrical distance, we can only guess at their physical locations in the protein. The amino acid sequences in the vicinity of the selectivity filter for representative glutamate receptor and K\(^{+}\) channel subunits are as follows:

In KcsA, Ba\(^{2+}\) binds to the channel at the juncture of the selectivity filter and the central cavity (Jiang and MacKinnon, 2000) near a threonine (Doyle et al., 1998). In the NMDAR NR1 subunit, the homologous residue in the sequence is an asparagine, the mutation of which has only a modest effect on Mg\(^{2+}\) block but substantially alters Ca\(^{2+}\) permeability (Burnashev et al., 1992; Wollmuth et al., 1998). The sequence of the NR2A subunit is not conserved, but mutation of the second of the vicinal asparagines has a strong inhibitory effect on Mg\(^{2+}\) binding (Mori et al., 1992; Sharma and Stevens, 1996a; Wollmuth et al., 1998). In terms of electrical distances, the Ba\(^{2+}\) site of potassium channels is \(\sim 30\%\) from the internal solution, whereas the Mg\(^{2+}\) site of the NMDAR is \(\sim 60\%\) from the external solution.

The location of the superficial external monovalent cation site is more difficult to pinpoint. It may be formed by the NH\(_2\)-terminal domain up to M1 and the M3-M4 linker (Beck et al., 1999), and may perhaps relate to external Zn\(^{2+}\)-binding residues (Fayyazuddin et al., 2000). The lack of voltage dependence in the occupancy of this site is different from that of the internal lock-in site of K\(^{+}\) channels, which are \(\sim 30\%\) through the field from the intracellular solution (Neyton and Miller, 1988).

The internal K\(^{+}\) site of NMDAR appears to be homologous to the external lock-in site of potassium channels, as both are \(\sim 15\%\) through the field from the closest bulk solution. In NMDAR, this site may be located in the filter or in an inner vestibule formed by M2 residues (Kuner et al., 1996). Mutation of the second glycine in the NR1 sequence, and the final asparagine in structural (Wood et al., 1995) and evolutionary (Chen et al., 1999) relationship between K\(^{+}\) channels (which are shaped like an inverted teepee; Doyle et al., 1998)
the NR2A sequence, reduces the channel conductance for outward current carried by Cs+ (Kupper et al., 1996), thus these residues are candidates for the internal site. Mutation of the glutamate in NR1 and the glutamine in NR2A (to lysine) also decreases block by internal Mg2+, but these residues are less attractive candidates because they are not accessible to intracellular sulfhydryl reagents (Kuner et al., 1996). A tryptophan residue in both NR1 and NR2 subunits modulates Mg2+ block (Williams et al., 1998) and may also influence the internal K+ site. In NMDAR, as in K+ channels, this lock-in site is more selective than the corresponding one on the other face of the permeation pathway.

Although the results and analyses clearly indicate that there are at least three K+ binding sites in the NMDAR channel (two external and one internal), there are certain inconsistencies in the parameter values that suggest that the situation is more complex. First, there is a substantial spread in the estimated rate constant for Mg2+ association in the absence of a membrane potential and competing ions. The value obtained from varying $[K^+]_{\text{ex}}$ was $2.0 \pm 0.1 \times 10^8 \text{M}^{-1}\text{s}^{-1}$ (Table IV), whereas that obtained from varying $[Na^+]_{\text{ex}}$ was $7.8 \pm 2.4 \times 10^8 \text{M}^{-1}\text{s}^{-1}$ (see Table I in Zhu and Auerbach, 2001, in this issue). Second, for both Na+ and K+, the apparent affinities of the external sites are higher for intra- versus extracellular ions. However, the parameters indicate that intracellular Na+ associates 8 times faster, whereas K+ associates 18 times faster than its extracellular counterpart, even though these two ions have similar reversal potentials and conductances (Zhu, Y., and A. Auerbach, unpublished observations). Third, the results show that whereas intracellular K+ has ready access to the external sites ($K_{\text{Mg,140}}^V = 8.3 \text{mM}$; Table III), extracellular K+ has an extremely low affinity for the internal site ($K_{\text{Na,internal}}^V = 16 \text{M}$; Table IV). We cannot give specific reasons for these inconsistencies. It is possible that Na+ and K+ can differentially alter the shape and/or properties of the permeation pathway via a direct interaction with the protein, as has been proposed for K+ channels (Imnke et al., 1999). In addition, it is likely that at least some of the basic assumptions of the analysis, e.g., discrete barriers, ion independence and single-filing, are not accurate in detail.

Comparison with Previous Results

Our results agree with those of Antonov et al. (1998) and Antonov and Johnson (1999) with regard to the number and the relative locations in the electric field of the NMDAR external monovalent ion-binding sites, and the effect of occupancy of these sites on the kinetics of Mg2+ blockade. One difference is that we observe that occupancy of an internal site by intracellular K+ accelerates Mg2+ dissociation limits Mg2+ permeation, whereas Antonov and Johnson (1999) did not observe any effect of intracellular Cs+ on the Mg2+ net unbinding rate constant. This difference can perhaps be traced to the difficulty in detecting the effect of intracellular monovalent ions on the kinetics of Mg2+ blockade. First, the increased rate of Mg2+ dissociation and decreased rate of Mg2+ permeation offset, to some extent. That is, the effect of intracellular permeant ions on the net Mg2+ release rate is small. Second, electrostatic repulsion between the bound Mg2+ and the ion at the internal site decreases the affinity of internal site. As a consequence, this site has a very low affinity for intracellular ions. Third, extracellular Na+ reduces Mg2+ dissociation by binding to the external site. Thus, in the presence of a high concentration of extracellular Na+, the enhancement of Mg2+ dissociation by the intracellular permeant ion is obscured. In our experiments, $[Na^+]_{\text{ex}}$ was low (50 mM), specifically to minimize this effect. Antonov and Johnson (1999) used a high $[Na^+]_{\text{ex}}$ (140 mM), which is perhaps the main reason why a change in the Mg2+ unbinding rate in different $[Cs^+]_{\text{in}}$ was not observed. Finally, given the high selectivity of the internal site for K+ over Na+, it is possible that this site has a low affinity for Cs+.

The Effect of Physiological Concentrations of Intracellular K+ on the Apparent Parameters of Mg2+ Block

In contrast to the voltage-independent binding of extracellular Na+ to the external sites, the binding of intracellular K+ to both the external sites and the internal site is voltage-dependent. Therefore, under physiological conditions, intracellular K+ will have a significant influence on the apparent voltage dependence of Mg2+ block.

In the presence of 140 mM K+ in the intracellular solution (and without any permeant ions in the extracellular solution), $k_{\text{Mg}}^{V}$ can be described by Eq. 5 (with $[Na^+]_{\text{ex}} = 0$). Using the values in Table I, we used this equation to compute apparent association rate constants in 140 mM intracellular K+ ($k_{\text{Mg,140}}^{V}$) between $-60$ to $-140$ mV. These were fitted by a standard exponential function to estimate the apparent voltage dependence ($\delta_{\text{Mg}}$):

$$k_{\text{Mg,140}}^{V} = k_{\text{Mg,140}}^0 e^{-\frac{-V_{\text{Mg,140}}}{\delta_{\text{Mg}}}}. \tag{11}$$

The fitted parameters were $k_{\text{Mg,140}}^0 = 1.4 \times 10^6 \text{M}^{-1}\text{s}^{-1}$ and $\delta_{\text{Mg}} = 0.75$. This voltage dependence is about threefold greater than the intrinsic voltage dependence of Mg2+ association ($\delta = 0.24$; see Zhu and Auerbach, 2001, in this issue). In 140 mM $[K^+]_{\text{in}}$, the Mg2+ association rate constant is only $\sim 0.2\%$ of its value in pure water at 0 mV, but it is 2% of this value at $-60$ mV. Physiological concentrations of intracellular K+ increase the apparent voltage dependence of Mg2+ association primarily as a consequence of voltage-dependent occupancy of the external site.
A similar approach was used to examine the effect of intracellular K\(^+\) on Mg\(^{2+}\) dissociation and permeation. The apparent Mg\(^{2+}\) dissociation rate is given by Eq. 2 (with [Na\(^+\)]\(_{ex}\) = 0). Using the values in Table I and this equation to compute \(k_{p0,Mg,140}\) values, and then fitting these by an exponential function (see Eq. 11), we estimate \(k_{p0,Mg,140}\) = 2.4 \times 10^5 s\(^{-1}\) and \(\xi_{140}\) = 0.40. Thus, 140 mM [K\(^+\)]\(_{in}\) alone increases the magnitude of the apparent Mg\(^{2+}\) dissociation rate constant approximately threefold (at 0 mV), but does not influence the apparent voltage dependence of this process (\(\xi = 0.35\); see Zhu and Auerbach, 2001, in this issue).

The effect of extracellular Na\(^+\) on Mg\(^{2+}\) permeation is small (see Zhu and Auerbach, 2001, in this issue). However, occupancy of the internal site by K\(^+\) prevents Mg\(^{2+}\) permeation, thus, the effect of intracellular K\(^+\) on Mg\(^{2+}\) permeation is expected to be significant. The apparent Mg\(^{2+}\) permeation rate constant is given by Eq. 3 (with [Na\(^+\)]\(_{ex}\) = 0). Proceeding as above, we estimate \(k_{p0,Mg,140}\) = 427 s\(^{-1}\) and \(\xi_{140}\) = 0.05. Thus, 140 mM [K\(^+\)]\(_{in}\) alone decreases the magnitude of the Mg\(^{2+}\) permeation rate by \(\sim 30\%\) of its value in pure water (at 0 mV), but has only a small effect on the apparent voltage dependence of this process \(\lambda = 0.35\); see Zhu and Auerbach, 2001, in this issue).

We combined the apparent values of the Mg\(^{2+}\) block to estimate an apparent Mg\(^{2+}\) equilibrium dissociation constant. The results were \(K_{p0,Mg,140}\) = 17 mM and \(\xi_{140}\) = 1.13, compared with the intrinsic values of 12 mM and 0.57, respectively (see Zhu and Auerbach, 2001, in this issue). Thus, 140 mM [K\(^+\)]\(_{in}\) alone causes a >1,400-fold increase in the apparent Mg\(^{2+}\) equilibrium dissociation constant (at 0 mV), and approximately doubles the voltage dependence of equilibrium blockade.

The results suggest that the three monovalent cation-binding sites in the NMDAR permeation pathway serve two basic functions. First, they contribute to the selectivity and the conductance of the channel to Na\(^+\) and K\(^+\) in ways that remain to be quantified. We hope that our results will serve as a guide for future studies of permeant ion movement through the NMDAR pore. Second, the equilibrium occupancies of the external and internal sites have a strong influence on the magnitude and voltage dependence of Mg\(^{2+}\) block. It is possible that fluctuations in the concentrations of Na\(^+\) and K\(^+\) in the synaptic gap and/or dendrite regulate the kinetics and equilibrium blockade of NMDAR at synapses.

We thank Thomas Kuner and Peter Seeburg for the rat NR1 and NR2A subunit cDNAs, and Jon Johnson for insightful comments on the manuscript.
