Single Cl\(^-\) Channels Activated by Ca\(^{2+}\) in Drosophila S2 Cells Are Mediated By Bestrophins

Li-Ting Chien, Zhi-Ren Zhang, and H. Criss Hartzell

Department of Cell Biology and Center for Neurodegenerative Disease, Emory University School of Medicine, Atlanta, GA 30322

Mutations in human bestrophin-1 (VMD2) are genetically linked to several forms of retinal degeneration but the underlying mechanisms are unknown. Bestrophin-1 (hBest1) has been proposed to be a Cl\(^-\) channel involved in ion and fluid transport by the retinal pigment epithelium (RPE). To date, however, bestrophin currents have only been described in overexpression systems and not in any native cells. To test whether bestrophins function as Ca\(^{2+}\)-activated Cl\(^-\) (CaC) channels physiologically, we used interfering RNA (RNAi) in the Drosophila S2 cell line. S2 cells express four bestrophins (dbest1–4) and have an endogenous CaC current. The CaC current is abolished by several RNAi constructs to dbest1 and dbest2, but not dbest3 or dbest4. The endogenous CaC current was mimicked by expression of dbest1 in HEK cells, and the rectification and relative permeability of the current were altered by replacing F81 with cysteine. Single channel analysis of the S2 bestrophin currents revealed an \(\sim2\)-pS single channel with fast gating kinetics and linear current–voltage relationship. A similar channel was observed in CHO cells transfected with dbest1, but no such channel was seen in S2 cells treated with RNAi to dbest1. This provides definitive evidence that bestrophins are components of native CaC channels at the plasma membrane.

INTRODUCTION

Age-related macular degeneration (ARMD) is one of the most common causes of blindness (Penfold et al., 2001), but its underlying mechanisms are not known. Although both genetic and environmental factors contribute to the pathogenesis of ARMD, some other forms of macular degeneration are inherited in a Mendelian fashion (Hartzell et al., 2005b). For example, Best vitelliform macular dystrophy (BVMD) (Godel et al., 1986) is linked to over 85 mutations, many of which are dominant, in the bestrophin-1 gene (VMD2) (Marquardt et al., 1998; Petrukhin et al., 1998; White et al., 2000; Weber and Krämer, 2002; Hartzell et al., 2005b; Strauss, 2005). Mutations in VMD2 are also associated with a small fraction of cases of adult onset vitelliform macular dystrophy (Allikmets et al., 1999; Krämer et al., 2000) and abnormal splice variants of VMD2 are associated with autosomal dominant vitreoretinocochoroidopathy (Yardley et al., 2004).

A defect in epithelial ion transport is thought to underlie BVMD because its hallmark feature is a decreased slow light peak in the electrooculogram (EOG) (Deutman, 1969; Cross and Bard, 1974; Wajima et al., 1993). Experiments in chicken, cat, and gecko show clearly that the light peak is caused by a Cl\(^-\) conductance in the basolateral membrane of the retinal pigment epithelium (RPE) (Gallemore et al., 1997).

The light peak is blocked by the Cl\(^-\) channel blocker DIDS, the reversal potential of the light peak equals \(E_{\text{Cl}}\), the reversal potential of the light peak changes in concert with \(E_{\text{Cl}}\), and the relative Cl\(^-\) conductance increases during the light peak. Because bestrophin-1 immunoreactivity is found basolaterally in RPE cells (Marmorstein et al., 2000; Bakall et al., 2003), the simplest hypothesis is that BVMD is caused by a defect in the basolateral RPE Cl\(^-\) channel that is mediated by bestrophin-1 (hBest1).

Strong support for this hypothesis was provided by the demonstration by Sun et al. (2002) that hBest1 and other bestrophins induce Cl\(^-\) currents when overexpressed in HEK cells. Furthermore, they showed that several of disease-causing mutations in hBest1 produce currents in HEK cells that are considerably smaller than normal (Sun et al., 2002). The bestrophins that have been studied are dependent on Ca\(^{2+}\) in the physiological range (Qu and Hartzell, 2003, 2004; Qu et al., 2004). Further evidence that bestrophins are Cl\(^-\) channels was provided by the demonstration that mutations in both hBest1 and mBest2 alter the relative anion conductance and permeability of the currents and change their sensitivity to cysteine-reactive reagents (Tsunenari

Abbreviations used in this paper: BVMD, Best vitelliform macular dystrophy; CaC, Ca\(^{2+}\)-activated Cl\(^-\); EOG, electrooculogram; hBest1, bestrophin-1; RPE, retinal pigment epithelium.
et al., 2003; Qu and Hartzell, 2004; Qu et al., 2004, 2006a). The ability to change bestrophin selectivity by mutations provides good evidence that bestrophin is responsible for forming the channel pore (Pusch, 2004). Despite these findings, the idea that hBest1 is an epithelial Cl\(^{-}\) channel has remained in doubt. The fact that several mutations in VMD2, like A243V, cause channel dysfunction in unambiguously identifying Cl\(^{-}\) channels. The Cl\(^{-}\) channel regulator hypothesis and the Ca\(^{2+}\) channel regulator hypothesis for bestrophin are not mutually exclusive. CFTR, for example, is a Cl\(^{-}\) channel that regulates a wide variety of different channels and transporters (Mehta, 2005).

Additional reasons to worry whether bestrophins are Ca\(^{2+}\)-activated Cl\(^{-}\) (CaC) channels are the findings that expressed bestrophin currents differ from native CaC currents (Pusch, 2004) and that mutations in mBest2 actually have somewhat unimpressive effects on anion selectivity (Qu et al., 2006a). These findings may suggest that the currents induced by bestrophin overexpression might be due to up-regulation of endogenous Cl\(^{-}\) channels. Up-regulation of endogenous Cl\(^{-}\) channels is a common response to over-expression of a variety of membrane proteins in Xenopus oocytes (Attali et al., 1995; Shimbo et al., 1995; Tzounopoulos et al., 1995). This has resulted in controversy about a variety of candidate Cl\(^{-}\) channels (Clapham, 1998; Jentsch et al., 2002; Hartzell et al., 2005a). For example, CLCA proteins have been proposed to be CaC channels (e.g., Cunningham et al., 1995; Yamazaki et al., 2005), but the prevailing view is that CLCAs are not Cl\(^{-}\) channels (Jentsch et al., 2002; Eggermont, 2004), partly because some CLCAs are secreted proteins (Gibson et al., 2005). This problem in unambiguously identifying Cl\(^{-}\) channels has arisen because it is difficult to separate endogenous and expressed currents; different Cl\(^{-}\) currents are often biophysically similar and very few specific blockers exist. The observation that wild-type mBest4 and hBest3 produce negligible Cl\(^{-}\) currents in a physiological voltage range when expressed in HEK cells raises additional questions about their role as Cl\(^{-}\) channels (Qu et al., 2006b).
At least part of the uncertainty surrounding bestrophin function exists because an endogenous bestrophin-associated current has not yet been described in any cell type. We have used Drosophila S2 cells to test whether bestrophins function as CaC channels natively and have characterized the single channel properties of these channels. These findings strongly support the conclusion that bestrophins are CaC channels.

MATERIALS AND METHODS

Solutions

Drosophila S2 cells were cultured in Schneider’s Drosophila Medium (GIBCO BRL) with 10% heat-inactivated FBS, 50 U/ml penicillin, and 50 μg/ml streptomycin in air at 22–24°C. HEK-293 cells and CHO cells (American Type Culture Collection) were cultured in Eagle’s Minimum Essential Medium with l-glutamine (Cellgro Co.), 10% heat-inactivated FBS (GIBCO BRL), and 50 U/ml penicillin and 50 μg/ml streptomycin (GIBCO BRL) in 5% CO₂/95% O₂ at 37°C. Transfection was done as described by Qu et al. (2004). The “zero” Ca²⁺ intracellular solution used for patch clamping S2 cells contained (in mM) 143 CsCl, 8 MgCl₂, 10 EGTA-NMDG, and 10 HEPES, pH 7.3 (NaOH) (free Ca < 20 nM). The “high” Ca²⁺ (4.5 μM free) intracellular solution was the same, except 10 mM EGTA-NMDG was replaced by 10 mM Ca-EGTA-NMDG. The Ca-EGTA-NMDG stock was prepared as described previously (Qu and Hartzell, 2000) according to Tsien and Pozzan (1989) and was estimated to have ~4.5 μM free Ca²⁺. The external solution used for patch clamp recording of S2 cells contained (in mM) 150 NaCl, 2 CaCl₂, 1 MgCl₂, 10 HEPES (pH 7.3 with NaOH), 15 sucrose, and 10 glucose. Osmolarity was adjusted with water or sucrose to 320 mOsM. For inside-out excised patch experiments, the patch pipet contained (in mM): 143 CsCl, 2 MgCl₂, 5 Ca-EGTA, 8 HEPES, 10 sucrose, and 10 glucose.

pH 7.3 with NMDG as described previously (Qu and Hartzell, 2004). HEK-293 extracellular solution contained 140 NaCl, 5 KCl, 2 CaCl2, 1 MgCl2, 15 glucose, and 10 HEPES (pH 7.4 with NaOH). Osmolarity was adjusted to 304 mOsm. Cl− currents would be expected to have reversal potentials near zero with these solutions, while cation currents would have extreme nonzero reversal potentials. Cells exhibiting nonzero reversal potentials were discarded.

Electrophysiology

Patch-clamp was performed at room temperature (22–24°C). Fire polished pipets pulled from borosilicate glass (Sutter Instrument Co.) had resistances of 2–3 MΩ for whole cell and 5–9 MΩ for single-channel recording when filled with intracellular solution. For whole-cell recording, cells were usually voltage clamped with 1-s duration ramps from −100 to +100 mV at 10-s intervals or 750-ms voltage steps from −100 mV to +100 mV in 20-mV increments. Whole cell recording data were filtered at 2–5 kHz and sampled at 5–10 kHz by an Axopatch 200A amplifier controlled by Clampex 8.2 via a Digidata 1322A data acquisition system (Axon Instruments Inc.). For single channel recording, pipets were coated with Sylgard, recordings were obtained with an Axopatch 200A amplifier, and data were filtered at 5–10 kHz and sampled at 20–50 kHz. In all cases, sampling was at least twice the filtering frequency. For analysis, single channel records were filtered digitally at 200 Hz with an 8-pole Bessel filter. Data were analyzed using pClamp 9 software and Origin 7.0 as described by Qu et al. (2004). Data are expressed as mean ± SEM.

Cloning Drosophila Bestrophin cDNAs

The sequences of the Drosophila bestrophins used in this study agreed with Genbank/EMBL/DDBJ sequences for dbest1 (AY061546), dbest2 (BT010012), dbest3 (AAF49648), and dbest4 (AAF49649). dbest1 and dbest2 full-length cDNAs were purchased from Drosophila Gene Collection (Lawrence Berkeley National Laboratory). The open reading frames were amplified by PCR and subcloned into the KpnI (5′) and NotI (3′) sites of pcDNA3.1 and sequenced.

RNA Interference

dsRNA was synthesized from dbest cDNAs. Control dsRNA was prepared from mBest2 intron 9. PCR primers (Table I) consisted of bestrophin gene-specific sequences with the 17 promoter sequence added to the 5′ ends (Van Gelder et al., 1990). Each primer was BLASTed against the Drosophila nucleotide database (NCBI) to ensure specificity. The PCR products were amplified with Pfx DNA polymerase (Invitrogen), gel-purified (QIAquick gel extraction kit, QIAGEN), and used for in vitro RNAi synthesis (mMESSAGE mMACHINE high yield capped RNA transcription kit, Ambion). RNAs were heated to 65°C for 10 min and annealed by slow cooling to room temperature. For RNAi transfection, 106 adherent S2 cells in a 35-mm Petri dish were washed twice with serum-free medium and incubated with 40 μg of dsRNA in 1 ml of serum-free medium for 30 min at room temperature. 2 ml of medium containing serum was then added and the cells cultured for 2–6 d.

Reverse Transcriptase PCR

The efficiency of gene silencing by RNAi was evaluated by reverse transcriptase PCR (RT-PCR). Total RNA was purified by the Trizol (Invitrogen) method. Bestrophin gene-specific primers were designed to span exon/exon boundaries to ensure that genomic DNA was not amplified (Table II). RT-PCR was conducted using SuperScript III One-Step RT-PCR with Platinum Taq (Invitrogen). PCR band densities were quantified using an Alphalmager Imaging System (Alpha Innotech). Each PCR band was excised, gel-purified, and cloned into pCRII-TOPO (Invitrogen) for sequencing.

Western Blot

Antibodies were raised in rabbits against amino acids 440–718 of dbest1 with (His)s tags. The construct for the His-tagged dbest1 (440–718) was made by amplifying the dbest1 nucleotide
sequence encoding amino acids 440–718 using Pfx polymerase and primers to which EcoRI (forward) and NotI (reverse) restriction sites had been added. The PCR product was then subcloned into EcoRI and NotI sites of pET28a (Novagen). Protein expression was induced in BL21 *Escherichia coli* by IPTG, the bacteria were lysed with Bug Buster Protein Extraction Reagent (Novagen), and the His-tagged protein purified by chromatography on a Ni-NTA-His bind affinity column (Novagen). For Western blot, a crude membrane fraction of S2 cells was separated by SDS-PAGE on 10% Tris-HCl polyacrylamide gels and blotted to PDVF membrane. The antibodies were used at 1:5,000 dilution and detected by enhanced chemiluminescence (Super Signal, Pierce Chemical Co.). The antibodies did not recognize a band in the dbest1 knockout fly (dbest1-2 and rescued λ5; dbest1-2 lines were obtained from G. Mardon, Baylor College of Medicine, Houston, TX).

**RESULTS**

**An Endogenous CaC Current in S2 Cells**

*Drosophila* S2 cells express an endogenous CaC current (Fig. 1). When S2 cells were whole-cell patch clamped with either 0 Ca\(^{2+}\) (<20 nM free) or high Ca\(^{2+}\) (∼4.5 μM) in the intracellular (pipet) solution, the currents observed with voltage ramps immediately after breaking the patch to initiate whole-cell recording were small, on average <250 pA (n = 52) at + 100 mV. When the pipet contained high [Ca\(^{2+}\)], the current ran up after patch break (Fig. 1, A, C, and F) with a half-time of ∼2 min and reached a plateau that was on average 17.1 ± 3.2-fold (mean ± SEM, n = 25) greater than the initial current. The mechanisms for the run-up remain unknown, but preliminary data suggest phosphorylation might be involved. The run-up was accelerated when Mg-ATP was included in the internal solution, and the run-up was blocked by staurosporin (unpublished data). The external solution contained glucose, so that the cell was capable of synthesizing ATP. In contrast, when the pipet solution contained 0 Ca\(^{2+}\), the currents remained stable after patch break (Fig. 1, B, C, and F). In some cells that were patched with zero Ca\(^{2+}\) pipet solution, the currents ran up for a short time and then ran down. The reason for this transient run-up is not known, but may be due to a spike of cytosolic Ca\(^{2+}\) associated with making or breaking the membrane patch. The currents stimulated by intracellular Ca\(^{2+}\) were carried by Cl\(^−\) ions, because they reversed near E\(_{Cl}\) (Fig. 1). The currents were unaffected by replacement of cations with NMDG\(^{+}\) and replacement of extracellular Cl\(^−\) with SO\(_{4}\)\(^{2−}\) abolished outward currents (unpublished data).

The currents recorded with high intracellular Ca\(^{2+}\) did not show any significant time-dependent activation or inactivation in response to voltage steps (Fig. 1, D and E). The currents had small voltage dependence at the extremes of the voltage range, which gave the I-V relationship a characteristic “S” shape (Fig. 1, A and E).

**S2 Cells Express Four Bestrophins**

To determine whether S2 cells express bestrophins, RT-PCR was performed with primers spanning exon–exon boundaries. Using several different sets of...

Endogenous S2 CaC Currents Are Abolished by Bestrophin-targeted RNAi

To test whether the S2 CaC current was mediated by bestrophins, we used RNAi. The first experiment was aimed at interfering nonselectively with all bestrophins. Bestrophin homologues are highly conserved in the first 360 amino acids, but are divergent in the C termini. bestrophins, dbest1 (AAR99659), dbest2 (AAF50668), dbest3 (AAF49648), and dbest4 (AAF49649) (Fig. 2 B). The sequences of the PCR products matched Genbank/EMBL/DDBJ sequences.

dsRNAs were synthesized to conserved N-terminal regions of dbest1 and dbest2 (Fig. 2 A; Table I). Four dsRNAs were made to regions encoding parts of the unique C termini of dbest1 (1S and 1C) and dbest2 (2S and 2C). Two others were made to regions of dbest3 (3C) and dbest4 (4C) that spanned conserved and unique regions. These dsRNAs reduced or eliminated the respective transcripts (Fig. 3 A).

dbest1 protein expression was measured by Western blot using an antibody developed against a fusion protein containing amino acids 440–718 of dbest1. To test whether the antibody was specific for dbest1, we compared immunoblots from flies in which the dbest1 gene was completely removed by recombination (dbest11-2 line, Tavsanli et al., 2001) with flies in which the knockout was rescued by a transposon containing an 18-kb genomic fragment encompassing the entire dbest1 gene (λ; dbest11-2 line, Tavsanli et al., 2001). The antibody recognized a band near the predicted size (79.6 kD) in rescued (Fig. 3 B) and wild-type (not depicted) flies. The band was absent in the dbest11-2 knockout flies (Fig. 3 B). These results show that the antibody was specific for dbest1 protein. In the S2 cells, a single dbest1 band was observed in cells treated with control RNAi and with dbest1-2S RNAi (Fig. 3 C). The dbest1 band was absent in S2 cells treated with dbest1-1S RNAi (Fig. 3 C). Because high-quality antibodies are not available for other Drosophila bestrophins, we were not able to assess effects of the other bestrophin RNAi constructs on protein levels. RNAi to dbest4 had inconsistent effects on dbest4 mRNA levels (unpublished data).

Each of the four RNAi constructs to dbest1 and dbest2 abolished CaC currents (Fig. 3 D). In Fig. 3 D, the final current amplitudes ~5 min after patch break are shown. However, in all cases, the current immediately after patch break was ~100 pA. In contrast to the absence of currents in cells treated with any of the dbest1 or dbest2 RNAi constructs, the RNAi constructs to dbest3 and dbest4 had no effect on CaC currents. The observation that the endogenous CaC current was significantly reduced by either dbest1 or dbest2 RNAi suggests that the current is composed of both dbest1 and dbest2 subunits.

Heterologous Expression of Drosophila Bestrophins in HEK-293 Cells

To test further whether Drosophila bestrophins are responsible for the S2 CaC current, HEK-293 cells were
transiently transfected with cDNAs encoding dbest1 or dbest2. Sun et al. (2002) have previously expressed dbest1 in HEK cells and showed that it induced Cl currents. In addition, we find that transfection of HEK cells by dbest1 alone reproduced the key characteristics of the endogenous CaC current in S2 cells. (a) The current activated slowly upon patch break with a half-time of ~2 min (Fig. 4, A and B). (b) The current had a characteristic “S” shaped I-V curve (Fig. 4, A and D). (c) The current was time independent and exhibited high current noise at negative membrane potentials (Fig. 4 C). (d) The permeability and conductance of SCN⁻ relative to Cl⁻ (P_{SCN}/P_{Cl} and G_{SCN}/G_{Cl}) were the same for the dbest1 current expressed in HEK cells and the endogenous S2 cell current (Fig. 5, B and C). P_{SCN}/P_{Cl} and G_{SCN}/G_{Cl} of dbest1 was different than what we have reported for wild-type mBest2 (Qu et al., 2004a) probably because there are four amino acids that we have shown are important in anion permeation in mBest2 that are different in dbest1. T87, L88, V89, and H91 in mBest2 are S88, I89, M90, and T92 in dbest1.

Somewhat surprisingly, expression of dbest2 alone did not induce a current (Fig. 4, B and D). However, a mixture of dbest1 and dbest2 produced currents that were similar to those produced by dbest1 alone (not depicted). The explanation for finding that dbest1 alone is sufficient to recapitulate the S2 current in HEK cells but that dbest1 and dbest2 RNAi abolish the S2 current is unknown. It is possible that dbest2 is not expressed or properly trafficked to the plasma membrane, but because we do not have an antibody for dbest2, this cannot be tested. Another possibility is that there is an endogenous bestrophin in HEK cells that can form a functional channel with dbest1 but not with dbest2. However, HEK cells do not express hbest1 or hbest2 (Fig. 4 E).

**Figure 6.** Single channel analysis of S2 bestrophin currents. (A) An inside-out excised patch was pulled from an S2 cell into 0 Ca²⁺ solution. During the break in the record, the solution was switched to one containing 650 nM free Ca. (B and C) Segments of the trace in A shown at higher time base as indicated. (D) All points histogram of the portion of the record in A between the arrows. (E) Time course of development of the current after addition of Ca²⁺. The current variance was calculated for 10-s segments of records from 29 patches at various times after Ca²⁺ addition.

**Mutagenesis Alters the Properties of dbest1 Currents**

To verify that the CaC currents in dbest1-expressing HEK cells were mediated by dbest1 and not by an upregulated endogenous channel, we changed phenylalanine 81 to cysteine (F81C) and examined the effect on the current. F81C was chosen because mutation of the homologous amino acid (F80) in mBest2 alters conductance and permeability (Qu and Hartzell, 2004). The F81C current inwardly rectified, in contrast to wild-type
Also, both $P_{SCN}/P_{Cl}$ and $G_{SCN}/G_{Cl}$ were increased by the F81C mutation (Fig. 5, C and D). The changes in $dbest1$ currents resulting from the mutagenesis supports the hypothesis that the currents were mediated by $dbest1$.

### Single-channel Analysis of Drosophila Bestrophin Currents

Having clearly identified the S2 CaC currents as being mediated by bestrophins, we set out to determine their single channel properties. A typical record of S2 bestrophin channels are shown in Fig. 6. Membrane patches were excised from S2 cells into 0 Ca$^{2+}$ solution and held at $V_m = -80$ mV. After ~20 s, the patch was switched to solution that contained Ca$^{2+}$. In the example, the channels did not start to become active until ~2 min after adding Ca$^{2+}$ (Fig. 6 A). Traces of this initial period of channel activation at higher sweep speed reveal individual channels with amplitudes of about ~0.2 pA (Fig. 6, B and C). The all-points histogram (Fig. 6 D) of this part of the trace shows peaks at ~0.2, ~0.4, and ~0.6 pA, which is consistent with at least three channels being active in the patch. After an additional 30–40 s in Ca$^{2+}$-containing solution, more channels became active and it was not possible to clearly resolve individual events.

Ca$^{2+}$ stimulated channel activity significantly in 29/32 patches. In some patches, the channel was present before adding Ca$^{2+}$, but the open probability was low and the channel usually disappeared after 1–2 min in zero Ca$^{2+}$ solution. Most patches contained >10 channels, so that isolated openings were resolved only during the initial period of activation. In about a third of the patches, it was not possible to resolve individual openings because too many channels were activated at once. But, even under these conditions, all-points histograms exhibited peaks separated by 0.15 to 0.2 pA at −80 mV, suggesting that the same unitary event was responsible for the activity that was observed.

The time course of channel activation was relatively slow, as suggested by the record in Fig. 6 A. To quantify the time course of activation, the variance of the current was measured at different times after introducing Ca$^{2+}$ and normalized to the variance before adding Ca$^{2+}$ (Fig. 6 E). The variance increased with a half-time of 63 s. This half-time was faster than we observed for the whole-cell currents in Fig. 1 (~2 min). However, the activation of the whole cell currents was measured in cells with no ATP in the internal solution, whereas excised patches were exposed to solutions that contained 3 mM ATP. In whole cell experiments, if ATP was added to the internal solution, the activation of the whole-cell current was accelerated approximately two-fold (unpublished data). In excised patch experiments, channels were activated in only a small fraction of patches that were exposed to high Ca$^{2+}$ without ATP in a 5-min time frame. This suggests that channel activation may involve other steps in parallel or series with Ca$^{2+}$ binding.

The single channel exhibited a linear I-V relationship (Fig. 7, A and B). This is different from the
sigmoid I-V relationship observed for the whole-cell S2 current, suggesting that the sigmoid nature of the whole cell current was related to channel gating. It was not practical to investigate channel gating quantitatively, however, because of the presence of multiple channels in the patch, the small size of the channels, and the short single channel open time. We estimated single channel open time in patches containing a few channels. Because it was necessary to filter the records at 200–300 Hz for analysis, channel open dwell times <1 ms were discarded. A fit of these data to a single exponential estimated a mean open time of ~1 ms at −80 mV.

To be certain that these channels were due to dBest1, we excised membrane patches from cells that had been treated with RNAi to dBest1 (1C) as in Fig. 3. The 2pS
channels described in Fig. 6 and 7 were rarely observed in patches from cells that were treated with RNAi to dbest1 (1C) (Fig. 8, A and B). In the example in Fig. 8, a few channel openings can be seen, showing that this patch was not simply an empty patch or a vesicle. Cells that were treated with control dsRNA had channels like those shown in Figs. 6 and 7.

As additional evidence that these channels are due to dbest1 expression, membrane patches were excised from CHO cells that had been transfected with dbest1 cDNA (Fig. 8, C–E). Single channels of ~2 pS conductance were observed in patches bathed in high Ca2+ solution. Similar channels were also observed in patches bathed in 0 Ca2+ solution, but at lower frequency. Fig. 8 D illustrates a feature of the gating of these channels that was typical both of the dbest1 channels in CHO cells and in native S2 cells. The channels appeared to gate in a cooperative fashion. During the burst at the start of the record in Fig. 8 D, three different levels of opening are evident (0.17, 0.34, and 0.51 pA; Fig. 8 E). The burst then ends and there are no channel openings for several seconds. In some records, this bursting activity seemed to involve as many as five individual channels, although quantitative analysis of these multichannel bursts was difficult. In any case, the results with RNAi treatment of S2 cells and overexpression of dbest1 in CHO cells provide strong arguments that these channels are responsible for the whole-cell bestrophin current in S2 cells.

**DISCUSSION**

The experiments in this paper add considerable strength to the hypothesis that bestrophins are indeed Ca2+-activated Cl− channels. The observation that we can abolish the native S2 CaC current with several different dsRNA constructs directed against dbest1 or dbest2, but not dbest3 or dbest4 is unambiguous evidence that bestrophins are essential components of CaC channels. Although this alone does not prove that bestrophins form the pore of the channel, the demonstration that expression of dbest1 in HEK cells induces a current with the same characteristics as the endogenous S2 CaC current and that mutation of F81 induces a current with the same characteristics as the demonstration that expression of dbest1 in HEK cells that bestrophins form the pore of the channel, the of CaC channels. Although this alone does not prove evidence that bestrophins are essential components or dbest2, but not dbest3 or dbest4 is unambiguous different dsRNA constructs directed against dbest1 can abolish the native S2 CaC current with several Ca2+ strengths to the hypothesis that bestrophins are indeed channels are responsible for the whole-cell bestrophin current in S2 cells.
