Kinetics of PIP$_2$ metabolism and KCNQ2/3 channel regulation studied with a voltage-sensitive phosphatase in living cells

Björn H. Falkenburger, Jill B. Jensen, and Bertil Hille
Department of Physiology and Biophysics, University of Washington, Seattle, WA 98195

The signaling phosphoinositide phosphatidylinositol 4,5-bisphosphate (PIP$_2$) is synthesized in two steps from phosphatidylinositol by lipid kinases. It then interacts with KCNQ channels and with pleckstrin homology (PH) domains among many other physiological protein targets. We measured and developed a quantitative description of these metabolic and protein interaction steps by perturbing the PIP$_2$ pool with a voltage-sensitive phosphatase (VSP). VSP can remove the 5-phosphate of PIP$_2$ with a time constant of $\tau < 300$ ms and fully inhibits KCNQ currents in a similar time. PIP$_2$ was then resynthesized from phosphatidylinositol 4-phosphate (PIP) quickly, $\tau = 11$ s. In contrast, resynthesis of PIP$_2$ after activation of phospholipase C by muscarinic receptors took $\sim 130$ s. These kinetic experiments showed that (1) PIP$_2$ activation of KCNQ channels obeys a cooperative square law, (2) the PIP$_2$ residence time on channels is $< 10$ ms and the exchange time on PH domains is similarly fast, and (3) the step synthesizing PIP$_2$ by PIP 5-kinase is fast and limited primarily by a step(s) that replenishes the pool of plasma membrane PI(4)P.

We extend the kinetic model for signaling from M$_1$ muscarinic receptors, presented in our companion paper in this issue (Falkenburger et al. 2010). Here, we determine the kinetics of production of PIP$_2$ generated by activation of plasma membrane receptors. Here, we determine the kinetics of production of PIP$_2$ generated by activation of plasma membrane receptors.

INRODUCTION

Phosphoinositides are minority phospholipids of biological membranes that are central in cellular signaling and as anchors for peripheral membrane proteins (e.g., De Matteis and Godi, 2004; Wenk and De Camilli, 2004). The signaling phosphoinositide phosphatidylinositol 4,5-bisphosphate (PIP$_2$), localized mainly in the cytoplasmic leaflet of the plasma membrane, is required for function of many ion channels and transporters (Hilgemann and Ball, 1996; Hilgemann et al., 2001; Suh and Hille, 2002, 2008). It is also important in exocytosis, endocytosis, cell adhesion, and motility (e.g., Di Paolo and De Camilli, 2006; Mao and Yin, 2007). Additionally, PIP$_2$ is the immediate precursor for three major second messengers, inositol 1,4,5-trisphosphate (IP$_3$), diacylglycerol (DAG), and phosphatidylinositol 3,4,5-trisphosphate, which are generated by activation of plasma membrane receptors. Here, we determine the kinetics of production of PIP$_2$ and its regulation of KCNQ2/3 (Kv7.2/7.3) potassium channels.

We have previously investigated signaling to KCNQ channels by the M$_1$ muscarinic receptor (M$_1$R). These studies established the requirements (Suh et al., 2004; Horowitz et al., 2005), timing (Jensen et al., 2009), and rate constants (see Falkenburger et al. in this issue) of individual steps in the M$_1$R signaling cascade: the binding of the muscarinic agonist oxotremorine-M (Oxo-M), the processing of G proteins on receptors, G protein dissociation/rearrangement, the binding of Go$q$ subunits to PLC, and PLC-mediated hydrolysis of PIP$_2$. The PIP$_2$ depletion turns off KCNQ2/3 potassium channels (diagramed in Fig. 1, A and B).

Recovery of current after M$_1$R activation requires regeneration of PIP$_2$. Wortmannin sensitivity and an ATP requirement implicate a type III phosphatidylinositol (PI) 4-kinase in the recovery (Suh and Hille, 2002; Zhang et al., 2003). The PI 4-kinases phosphorylate PI at the inositol 4 position to produce PI(4)P, which is then phosphorylated by phosphatidylinositol 4-phosphate (PIP) 5-kinases at the 5 position to yield PIP$_2$ (Fig. 1 E). These two steps are required for the maintenance of the “hormone-sensitive” pool of PIP$_2$ at the plasma membrane (Nakanishi et al., 1995; Wang et al., 2004) and for its recovery after receptor activation.

Here, we seek a quantitative description of the lipid kinases and phosphatases that govern plasma membrane PIP$_2$. Most interesting is PIP 5-kinase, the enzyme producing PIP$_2$, which also mediates the effects of Rho family GTPases on actin organization (Chong et al., 1994;
Oude Weernink et al., 2004). To perturb the system, we characterized and exploited a PIP$_2$ 5-phosphatase that can be activated by depolarization of the membrane potential, the voltage-sensitive phosphatase (VSP). VSP contains a voltage sensor domain homologous to those of voltage-gated ion channels and a phosphatase domain homologous to PTEN, a polyphosphoinositide phosphatase (Fig. 1, C and D) (Okamura et al., 2009). VSP can dephosphorylate P$_{(4,5)}$P$_2$ to P$_{(4)}$P (Iwasaki et al., 2008; Halasovich et al., 2009). Recovery after VSP activation is then mediated by the endogenous PIP$_5$-kinases at the plasma membrane. As VSP-induced changes in PIP$_2$ were not accompanied by the generation of other second messengers that might modulate KCNQ2/3 current, this intervention also provided an opportunity to learn more about the interaction of PIP$_2$ with KCNQ2/3 channels, and about PIP$_2$ reporting by the pleckstrin homology (PH) domain probe we use.

### MATERIALS AND METHODS

#### Cell culture and plasmids

Cells (tsA201) cultured in DMEM (Invitrogen) with 10% serum and 2% penicillin/streptomycin were passaged once a week. Cells were transfected at 75% confluency, plated on polylsine-coated glass chips 24 h after transfection, and used for experiments the next day. Cells were transfected with Lipofectamine 2000 (10 µl for a 3-cm dish; Invitrogen) and 0.5–1.2 µg DNA per plasmid: mouse M1R (provided by N. Nathanson, University of Washington, Seattle, WA); human eCFP-PH(PLCδ1) and eYFP-PH(PLCδ1); provided by K. Jalink, The Netherlands Cancer Institute, Amsterdam, Netherlands; human KCNQ2 and rat KCNQ3 (provided by D. McKinnon, State University of New York, Stony Brook, NY); PIP$_5$-kinase type 1y (provided by Y. Aikawa and T.F. Martin, University of Wisconsin, Madison, WI); and Gt-VSP-IRES-GFP (Gt-VSP, VSP from Ciona intestinalis; internal ribosome reentry site [IRES]) and Dr-VSP-IRES-GFP (Dr-VSP) from zebrafish (Danio rerio, both provided by Y. Okamura, Osaka University, Osaka, Japan). “Dark” Dr-VSP (without IRES-GFP) was generated by subcloning the Dr-VSP cassette into pcDNA3.0 using HindIII and XhoI.

#### Electrophysiology

Cells were continuously superfused with Ringer’s solution containing (in mM): 160 NaCl, 2.5 KCl, 2 CaCl$_2$, 1 MgCl$_2$, 10 HEPES, and 8 glucose, pH 7.4 (NaOH). 10 µM Oxo-M was applied via a two-barrel theta tube. Cells were recorded by whole cell gigaseal from Ciona intestinalis; internal ribosome reentry site [IRES]) and Dr-VSP-IRES-GFP (Dr-VSP) from zebrafish (Danio rerio, both provided by Y. Okamura, Osaka University, Osaka, Japan). “Dark” Dr-VSP (without IRES-GFP) was generated by subcloning the Dr-VSP cassette into pcDNA3.0 using HindIII and XhoI. Currents were filtered at 2.9 kHz. Sample intervals ranged from 20 mV for 300 ms and held at 120 mV (as in Hossain et al., 2008); and linear leak and capacitive transients were subtracted by a p/5 procedure (five repetitions of 0.2 of the test pulse amplitude from a holding potential of −120 mV after the test pulse).

KCNQ2/3 current was measured in two ways. One was to hold the membrane potential at −20 mV continuously. Endogenous currents in tsA201 cells are small at −20 mV (−26 pA ± 5 pA; n = 16 cells; see Fig. 52, A and C). The second method used tail currents. Every 0.5 or 1 s, the membrane potential was depolarized to −20 mV for 200 or 300 ms and repolarized to −60 mV. KCNQ2/3 current activates slowly upon depolarization and deactivates slowly upon repolarization (see Fig. 52 B). In contrast, endogenous currents deactivate too fast to be seen at the sampling frequency used. KCNQ2/3 tail currents were measured by comparing current at 20 and 200 ms after repolarization to −60 mV.

#### Photometric measurement of PH domain Förster resonance energy transfer (FRET)

We used epifluorescence photometry to measure the FRET of PH domains simultaneously with measurement of KCNQ2/3 current. The photometry setup was different from that used previously (Jensen et al., 2009; Falkenburger et al., 2010). A monochromator (Polychrome IV; TILL Photonics) provided excitation light, and a three-color dichroic mirror in the microscope reflected at 440, 500, and 580 nm (CFP, YFP, and mCherry; Chroma Technology Corp.). The dichroic mirror is transparent at 460–480 and 520–560 nm. Fluorescence was detected by a photometry system consisting of a ViewFinderIII with two photodiodes connected to an FDU-2 detection unit (TILL Photonics). Light was split between the two photodiodes by a dichroic mirror (DCLP505). In addition, the short-wavelength channel contained a D480/40 emission filter, and the long-wavelength channel contained an ET535/30 filter (Chroma Technology Corp.). For near-simultaneous acquisition of CFP; (440-nm excitation and 480-nm emission), YFPc (440-nm excitation and 535-nm emission), and YFPd (500-nm excitation and 535-nm emission), the excitation wavelength was scanned from 300 to 500 nm in 200 ms. Both photodiodes were sampled every 0.1 ms. A shutter was opened 10 ms before scanning and closed 100 ms after scanning. To measure KCNQ2/3 current at the same time, the membrane potential was depolarized to −20 mV for 300 ms and held at −60 mV for the remainder of the time. This protocol was repeated every 500 ms. After recording from each cell, an area of the coverslip without cells was measured as background. This background fluorescence was small and depended little on the excitation wavelength. The light intensity in the illuminated 139 × 158.5 µm$^2$ area was 45 µW at 430 nm and 35 µW at 500 nm (~0.2 W/cm$^2$).

Data were analyzed offline in Igor Pro 6.0. To calculate FRET, we extracted three values from each wavelength scan, similar to a three-cube FRET approach. We denote them CFPc, raw YFPc, and YFPc with the first part referring to the emission wavelength and the subscript referring to the excitation wavelength. For the CFPc value, emission in the short-wavelength channel (460–480-nm emission) was integrated over the time where excitation was 490–500 nm. The excitation wavelength was scanned from 300 to 500 nm in 200 ms. Both photodiodes were sampled every 0.1 ms. A shutter was opened 10 ms before scanning and closed 100 ms after scanning. To measure KCNQ2/3 current at the same time, the membrane potential was depolarized to −20 mV for 300 ms and held at −60 mV for the remainder of the same time. For the YFPc value, the long-wavelength channel was integrated over the time where excitation was 490–500 nm. The units for all three values were set as arbitrary fluorescence units (AFU). Background was subtracted from each. The raw YFPc value had to be corrected for cyan fluorescent protein (CFP) emission collected in the long-wavelength channel and for direct excitation of yellow fluorescent protein (YFP) by 440-nm light by subtracting 0.834*CFPc and 0.065*YFPc. The corrected value is referred to as YFPc from now on. The correction factors were determined by measuring cells expressing only CFP or YFP. The spectral window for collection of CFP emission was smaller than 180 HEPES, 75 NMDG, 1 CaCl$_2$, 1 MgCl$_2$, and 10 glucose, pH 7.4.
in our previous work (Jensen et al., 2009). Therefore CFPc had to be multiplied by a larger factor in correcting the long-wavelength channel for bleedthrough of CFP emission. The lower values for CFPc also affected the values of the FRET ratio, FRETr (see below). FRET was expressed as the ratio FRETr = YFPc/CFPc. This ratio is related to FRET efficiency, with two differences. A FRET efficiency of 20% means that 20% of CFP excitation is reemitted by YFP instead of CFP; thus CFP emission is reduced to 80%. If the short-wavelength detector (CFPc) and the long-wavelength detector (YFPc) had the same photon sensitivity, a FRET efficiency of 20% would correspond to a FRETr of 20/80 = 0.25. However, in the photometry setup used here, the absolute changes in YFPc were approximately threefold larger than the accompanying changes in CFPc (both in ΔAFU; compare Fig. 2, D with E). A true FRET efficiency of 20% would therefore correspond to a FRETr of 3*20/80 = 0.75. We report FRETr in arbitrary units because the absolute values will differ between setups.

The YFPc value should be unaffected by FRET. It showed a gradual decline over time, reflecting dialysis of the PH probes from the cell into the much larger patch pipette. The time constant of decline (~5 min) was similar to that for CFP protein diffusing from the patch pipette into the cell. The same decline was seen in the CFPc channel. Finally, as a consequence of the increasing distance between donors and acceptors, their FRET interaction also showed some decline.

Modeling
A kinetic model of phosphoinositide metabolism was formulated as a compartmental model in the Virtual Cell framework (University of Connecticut). The Virtual Cell Model “Falkenburger JGP2010” is publicly available at http://www.vcell.org/ under shared models/hillelab.

Statistics
Summarized data include one data point per cell. Bars and markers represent mean ± SEM.

**RESULTS**

Our laboratory has already formulated a preliminary kinetic description of the signaling steps from muscarinic receptor excitation to PIP2 turnover and channel modulation (Suh et al., 2004). It was based on plausible estimates knowing the final modulation of KCNQ2/3 channels. Then, a second-generation model for the steps from receptor activation to turning on PLC was formulated in our companion paper (Falkenburger et al., 2010) based on our recent more complete set of kinetic measurements with FRET (Jensen et al., 2009). In this paper, to extend our model to include the steps of PIP2 metabolism and the action of PIP2 on channels, we have made extensive use of PH domains as indicators of PIP2, of a VSP to deplete PIP2 rapidly, and of KCNQ2/3 channels to report their own activation by PIP2. We start by characterizing VSP.

The voltage sensor of VSP responds rapidly
As in voltage-gated ion channels, positive charges in the S4 segment of the voltage sensor of VSP (Fig. 1, C and D, **Figure 1.** M1R signaling and phosphoinositide metabolism. (A) Neuronal M current is mediated by KCNQ2/3 potassium channels (yellow), which require membrane depolarization and PIP2 to open. (B) Binding of the M1R agonist Oxo-M facilitates binding of G proteins to the receptor. This binding induces “activation” of G proteins, i.e., nucleotide exchange at the Gαi subunit from GDP to GTP, and dissociation of Gα from Gβγ. Gαi GTP activates PLC, which cleaves PIP2 into DAG and IP3. The absence of PIP2 prevents KCNQ2/3 channels from opening. (C) Voltage-gated ion channels are tetramers. Each subunit consists of a four-segment (S1-S4) voltage sensor domain (green and yellow) and a pore-forming domain (dark red). The S4 segment (yellow) contains positive charges, which move upon depolarization. (D) VSPs are monomers. They contain a four-segment voltage sensor and a phosphatase domain. The phosphatase is activated by depolarization and dephosphorylates PIP2 to PI(4)P. (E) Phosphoinositide metabolism. PI is phosphorylated first by a PI 4-kinase and then by a PIP 5-kinase to yield PI(4,5)P2. A 4-phosphatase and a 5-phosphatase mediate the reverse reactions. VSP is a 5-phosphatase.
yellow) move outward upon depolarization, making a transient outward current, termed “gating current” for ion channels and “sensing current” for this nonchannel enzyme. The charge movement leads to activation of the phosphatase activity (Murata et al., 2005; Murata and Okamura, 2007). We determined the voltage dependence of the charge movement and its time course for VSP from zebrafish (Dr-VSP) and *Ciona* (Ci-VSP) expressed in tsA201 cells (Fig. S1). Depolarization for 100 ms elicited an outward sensing current, and repolarization elicited an inward current. The integrals over both segments were equal and represent the total charge moved during voltage sensing. At +100 mV with Dr-VSP, for example, the exponential time constant decay of the major sensing current was $\tau = 39 \pm 4$ ms ($n = 4$ cells), and on return to $-60$ mV, the return charge flowed with time constant $\tau = 8.6 \pm 1.1$ ms ($n = 5$ cells), in full agreement with Hossain et al. (2008). We did not attempt to resolve additional slow time constants reported by others (Villalba-Galea et al., 2008). For Dr-VSP, the voltage dependence of this sensing charge (the Q-V curve) followed a Boltzmann relation, with a midpoint at +100 mV and a slope factor of 1.5 elementary charges. From this, Dr-VSP would be inactive at $-20$ mV, where we measure KCNQ current. A depolarization to +100 mV moves 50% of VSP-sensing charge and is well tolerated by our cells. By comparison, the voltage dependence of Ci-VSP was left-shifted and less steep. These findings agree with previous measurements of VSP-sensing currents (Hossain et al., 2008). To ensure that VSP remained inactive at $-20$ mV in our experiments, we subsequently used only Dr-VSP.

Total sensing charge also provides an estimate of the density of VSP molecules in transfected cells. The VSP construct we used included GFP after an IRES, so transfected cells would likely express more copies of VSP than of GFP. We chose cells by their visible GFP fluorescence (Fig. 2 D), (2) a decrease in YFPC fluorescence (Fig. 2 E), (3) little change in YFPY fluorescence (Fig. 2 F), and (4) a strong reversible drop in FRETr (Fig. 2 G). Thus, in a few hundred milliseconds we could convert most of the membrane PIP$_2$ to PI(4)P, and in 10–20 s the PIP$_2$ was restored.

Others have made kinetic models of the conformational changes of VSP, combining observations of charge movement and of signals from various attached fluorescent labels (Villalba-Galea et al., 2008; Akemann et al., 2009). They include fast conformational changes and sometimes several slower steps. The constructs they studied had the phosphatase enzyme mutated to be inactive or entirely deleted and sometimes replaced by one or two fluorescent proteins. None of these models gives direct information about how soon the phosphatase activity is turned on after the initial major charge movement occurs. However, our experiments below suggest that the enzyme activity is nearly synchronous with or follows charge movements within tens of milliseconds. For simplicity, we refer to our standard +100-mV depolarizations as “VSP activation.”

**Activation of VSP reduces PIP$_2$ and KCNQ2/3 current**

We now use VSP activation to perturb the endogenous plasma membrane PIP$_2$ pool. To measure PIP$_2$ depletion during VSP activation, we used FRET between two fluorescently labeled PH domains from PLC81 (PH-CFP and PH-YFP) as described previously (van der Wal et al., 2001; Jensen et al., 2009). PH probe FRET reports PIP$_2$ surface density because binding to PIP$_2$ at the plasma membrane brings the CFP and YFP close enough together for FRET to occur. FRET between these probes decreases as PIP$_2$ is depleted and increases as PIP$_2$ recovers (Fig. 2, A–C, and Materials and methods). To calculate FRET, we measured three values (CFP$_c$, raw YFP$_c$, and YFP$_t$) during VSP activation, made corrections, and calculated the FRET ratio FRET$_r$ = YFP$_c$/CFP$_c$ as described in Materials and methods. Upon activation of VSP by depolarization to +100 mV for 2 s, PIP$_2$ was depleted, and we observed (1) an increase in CFP$_c$ fluorescence (Fig. 2 D), (2) a decrease in YFP$_c$ fluorescence (Fig. 2 E), (3) little change in YFP$_t$, fluorescence (Fig. 2 F), and (4) a strong reversible drop in FRET$_r$ (Fig. 2 G). FRET$_r$ fell almost to zero during VSP activation, suggesting that much of PIP$_2$ was lost in that time. The mean ON time constant of the VSP-induced depletion was 421 ms at +100 mV, and the mean recovery time constant after repolarization was 6.5 s at $-60$ mV (Fig. 2, I and J). Thus, in a few hundred milliseconds we could convert most of the membrane PIP$_2$ to PI(4)P, and in 10–20 s the PIP$_2$ was restored.

The relationship between membrane PIP$_2$ and PIP$_2$-sensitive KCNQ current was revealed by coexpressing KCNQ2/3 potassium channels with VSP. Initially, KCNQ2/3 current was measured by the tail current amplitude (see Materials and methods). The fluorescence and current traces in Fig. 2 (D–H) were recorded simultaneously during depletion of PIP$_2$. Activation of VSP decreased the KCNQ2/3 tail current quickly (Fig. 2 H),
as reported previously (Murata and Okamura, 2007). When VSP was turned off again, the recovery of current was slower than recovery of PH probe FRET (compare Fig. 2, H with G).

To quantitate the kinetics of VSP actions on KCNQ2/3 current, we switched to measuring current by holding continuously at −20 mV, where noninactivating KCNQ2/3 current can be maintained for a long time and other endogenous K+ currents in tsA201 cells are minimally activated (Fig. S2, A and D). PH probes were not expressed in these experiments. VSP was activated by brief steps to +100 mV, a perturbation that also increased the driving force for K+ and, in cells without VSP, increased current through KCNQ2 and endogenous channels (Fig. 3 A). When Dr-VSP was coexpressed (Fig. 3 B), KCNQ2/3 current decayed during the +100-mV depolarization. Current was much reduced upon return to −20 mV and recovered thereafter. We compared currents at −20 mV before and after varying lengths of VSP activation to track the onset of the VSP effect (Fig. 3, C and D).
104 Kinetics of PIP$_2$ metabolism

explains why the onset of VSP action on current is faster than that on FRETr. If the decay of FRETr followed an exponential time course with time constant $\tau$, the square of this function would decay exponentially with a time constant of $\tau^2$. It also explains why recovery of current is S-shaped and slower than FRETr when fitted with a single exponential (Fig. 4 D). If FRETr recovery followed $y = 1 - \exp(-t/\tau)$, current recovery would follow $y^2 = 1 - 2\exp(-t/\tau) + \exp(-2t/\tau)$, which is S shaped. As predicted by that equation, our recovery data fitted with the double-exponential equation gave mean time constants of 3.1 s for the positive term and 6.8 s for the negative term (Fig. 4 C, inset; 30 cells). This relationship allows us to predict the dependence of KCNQ2/3 current on PIP$_2$ density from the known PIP$_2$ affinity of PH probes (Fig. 4 G; for details see Fig. S3), and suggests that more than one PIP$_2$ molecule binds to activate a KCNQ2/3 channel.

Interestingly, in a few cases (7/31 cells) KCNQ2/3 current recovered after VSP activation to values $\sim$10% higher than the steady-state value before VSP activation. Such over-recovery was observed both with holding at $-20$ mV and with tail currents. We have so far not investigated what underlies this phenomenon.

Recovery after VSP activation reflects PIP$_2$ 5-kinase activity

The observations so far might be interpreted in two ways. The straightforward model would be that while VSP is converting PIP$_2$ into PIP, the depletion of PIP$_2$ turns off the KCNQ2/3 channels, with a corollary that

$\sim$120 ms, and significant effect was already evident with only 40 ms of VSP activation, just enough time for 63% movement of the voltage sensor charge (Fig. S1 A). Thus, the coupling of the VSP voltage sensor to the phosphatase activity and the reporting of PIP$_2$ depletion by KCNQ2/3 current are both fast ($<40$ ms). Fitting exponentials to the decline of whole cell current at +100 mV (Fig. 4 A) gave a time course for the action of VSP consistent with that of Fig. 3 D, even though this measure would be contaminated by the slow activation of KCNQ2/3 current and the inactivation of endogenous currents at +100 mV (Fig. S2, A and B).

KCNQ2/3 current is proportional to the square of PH domain FRET

Now we can consider the relationship between PIP$_2$ and current. During and after VSP activation, the changes of KCNQ2/3 current and those of the PH domain FRETr were not linearly related to each other. First, their exponential time constants differed systematically. For the onset of inhibition, current decayed faster than FRETr, whereas for the recovery, current returned more slowly than FRETr (Fig. 4, A and B). The recovery of current followed an S-shaped time course (Figs. 2 H, 3 B, and 4 C), and when current was plotted against FRETr, the relationship was fitted better by a square law than by a straight line or cubic curve (Fig. 4 E). The same relationship was seen during recovery after M$_2$R activation (Fig. 4 F, data taken from Jensen et al., 2009). This dependence of KCNQ2/3 current on the square of PH probe FRETr explains why the onset of VSP action on current is faster than that on FRETr. If the decay of FRETr followed an exponential time course with time constant $\tau$, the square of this function would decay exponentially with a time constant of $\tau^2$. It also explains why recovery of current is S shaped and slower than FRETr when fitted with a single exponential (Fig. 4 D). If FRETr recovery followed $y = 1 - \exp(-t/\tau)$, current recovery would follow $y^2 = 1 - 2\exp(-t/\tau) + \exp(-2t/\tau)$, which is S shaped. As predicted by that equation, our recovery data fitted with the double-exponential equation gave mean time constants of 3.1 s for the positive term and 6.8 s for the negative term (Fig. 4 C, inset; 30 cells). This relationship allows us to predict the dependence of KCNQ2/3 current on PIP$_2$ density from the known PIP$_2$ affinity of PH probes (Fig. 4 G; for details see Fig. S3), and suggests that more than one PIP$_2$ molecule binds to activate a KCNQ2/3 channel.

Interestingly, in a few cases (7/31 cells) KCNQ2/3 current recovered after VSP activation to values $\sim$10% higher than the steady-state value before VSP activation. Such over-recovery was observed both with holding at $-20$ mV and with tail currents. We have so far not investigated what underlies this phenomenon.

Recovery after VSP activation reflects PIP 5-kinase activity

The observations so far might be interpreted in two ways. The straightforward model would be that while VSP is converting PIP$_2$ into PIP, the depletion of PIP$_2$ turns off the KCNQ2/3 channels, with a corollary that
PI(4)P and the activity of cellular PIP 5-kinase(s) are needed after VSP activation to restore PIP2 and full channel activity.

PI(4)P is unable to support activity of the channels. An alternative model would be that channels are directly inhibited by the accumulating pool of PI(4)P rather than by depletion of PIP2. These possibilities might be distinguished by overexpressing an exogenous PIP 5-kinase to increase tonic PIP2 levels. In the first model, the increased PIP2 would make it harder for VSP to deplete PIP2 quickly and to turn off channels. In the second model, increased PIP2 might even result in intensified channel inhibition by providing a larger precursor pool for production of inhibitory PI(4)P. As predicted in the first model, the transfected 5-kinase made activation of VSP much less effective at suppressing KCNQ2/3 current (Fig. 5). The relation between the duration of VSP activation and current inhibition was slowed eightfold (Fig. 5, A and B), whereas recovery after VSP activation was speeded fivefold (Fig. 5, A and C). PH probes were not expressed in these experiments. These findings support the concepts that PIP2 is essential, PI(4)P does not inhibit or permit channel activity, and PI(4)P and the activity of cellular PIP 5-kinase(s) are needed after VSP activation to restore PIP2 and full channel activity.

Phosphorylation of PI(4)P by PIP 5-kinase is faster than PI(4)P supply by PI 4-kinase

In contrast to VSP, PLC degrades PIP2 to DAG and IP3 and also leads to quick PI(4)P depletion (Willars et al., 1998; Horowitz et al., 2005). Recovery after PLC activation needs two steps for PIP2 resynthesis: first, phosphorylation of PI by a PI 4-kinase, and then phosphorylation of PI(4)P by a PIP 5-kinase. We find that recovery of KCNQ2/3 current at −20 mV was fitted with a double exponential: y = a − b*exp(−c*t) + d*exp(−f*t). (Inset) Summary of time constants from 31 cells. Time constant of the positive term (pos.) is 1/f, and that of the negative term (neg.) is 1/c. (D) Illustration of the consequence of squaring an exponential of the form y = 1 − exp(−t/τ). (E) Plot of KCNQ2/3 current at −20 mV versus averaged FRET at the same time after M1R activation, measured in separate cells (data from Figs. 5 D and 7 B in Jensen et al., 2009). (G) Illustration of the dependence of FRET on PH probe concentration as predicted by the model outlined in Fig. 7 and Tables I and II: Kd of PH probe is 2,000 µm−2 for PIP2 and 0.1 µM for IP3 (0.16 µM IP3); Ks of KCNQ is 2,000 µm−2 for PIP2. KCNQ current = (KCNQ_PIP2)2.
We now return to a quantitative description of the signaling kinetics. For our model of phosphoinositide metabolism (Fig. 7, Tables I and II, and Table S1), we assumed that all phosphoinositide reactions take place in one compartment, and that the relevant kinases and phosphatases obey nonsaturating linear kinetics. For off of PLC after agonist wash off because the measured interaction of Gq with PLC falls by 95% in only 2 s (Jensen et al., 2009; Falkenburger et al., 2010). Apparently, the production of PI(4)P by PI 4-kinase is rate limiting for recovery after M1R stimulation, and the endogenous PIP 5-kinase is many-fold faster than the PI 4-kinase.

Figure 5. PIP 5-kinase overexpression antagonizes VSP effects. (A) Traces from two cells with similar current amplitudes transfected with Dr-VSP and KCNQ2/3 (ctrl., black trace) or with Dr-VSP, KCNQ2/3, and PIP 5-kinase Iy (+5K, red trace). (B) Dependence of current inhibition on the duration of VSP activation. Baseline-normalized currents at −20 mV immediately after VSP activation are plotted for control (from Fig. 3 D) and +5K (three cells). (C) Time constants of single-exponential fits to current recovery after VSP activation. Summary of 16 cells for control and 4 cells for +5K.

Figure 6. PIP 5-kinase is faster than PI 4-kinase. Tail current amplitudes were used to measure current inhibition by Dr-VSP or M1R activation and its recovery. (A) Time course of tail current amplitude in a cell transfected with Dr-VSP and KCNQ2/3 (2 points s⁻¹). (B) Superimposed currents at time points before VSP activation (a), after VSP activation (b), and during recovery (c). (C) Summary of tail current amplitudes relative to baseline after VSP activation (b/a) and after recovery (c/a). (D) Time constant of a single-exponential fit to the recovery time course (time b to c). (C and D) Summaries of 19 cells. (E) Time course of tail current amplitudes in a cell transfected with M1R and KCNQ2/3 (1 point s⁻¹). (F) Superimposed currents at time points a, b, and c indicated in E. (G) Tail current inhibition by M1R activation (summary of 10 cells). (H) Time constant of an exponential fit of recovery (summary of seven cells).
by M\(_1\)Rs was determined by the model described in our companion paper (Falkenburger et al., 2010), which among other things reproduces time course and Oxo-M concentration–response curves for the interaction of Goq with PLC as measured by FRET (Jensen et al., 2009). As before, our model does not include the well-known contribution of Ca\(^{2+}\) as a necessary cofactor in PLC stimulation by Goq (Horowitz et al., 2005).

We began with VSP. It was simple to pick a rate constant for VSP activity that reproduced the rapid time course of KCNQ current inhibition during VSP activation (Fig. 8 A). Then, it was straightforward to set the rate of the endogenous PIP\(_2\) 5-kinase to reproduce current recovery from VSP, which takes \(\sim 11\) s (Fig. 8 B). This gave us two rate constants and good agreement with the VSP experiments. Fig. 8 C illustrates the decline in PIP\(_2\) and parallel rise in PI(4)P during VSP activation and their recovery hereafter. The choice of PIP\(_2\) 5-kinase rate constant did depend on the uncertain size of the resting PI(4)P pool relative to the PIP\(_2\) pool. If the resting PI(4)P pool was relatively small, the PIP\(_2\) 5-kinase rate constant would have to be a little faster than if the pool was of comparable size to PIP\(_2\) (see Discussion). The new experiments (Fig. 3) also showed that the interaction of PIP\(_2\) with KCNQ channels must be more rapid than we assumed previously.

We then considered strong activation of PLC by M\(_1\)R activation. Again, we could easily pick a rate constant for PLC acting on PIP\(_2\) to match the rate of current inhibition by 10 \(\mu\)M Oxo-M (Fig. 9 A, red solid line). Given a target pool size for PI(4)P and the rate constant for the PIP\(_2\) 5-kinase, we could also pick a rate constant for the PI 4-kinase to match the slow recovery from Oxo-M (Fig. 9 B, red solid line). This gave us two more rate constants and a reasonable fit.

Next, we turned to weaker activation of PLC by M\(_1\)R activation with subsaturating agonist concentrations.

108 Kinetics of PIP2 metabolism

green dashed line in Fig. 9 (A–C). In this simulation, the synthesis of new PIP2 is accelerated several-fold during the Oxo-M application as several authors have already suggested (see Discussion and legend to Fig. 9). Accelerated synthesis counters the PIP2 depletion catalyzed by weak activation of PLC.

Finally, we considered the actions of Oxo-M on FRET from PH domain probes. The unchanged model (red solid lines) simulates the decrease of FRETr with 10 µM Oxo-M well (Fig. 9 D), and the concentration–response curve moderately well (Fig. 9 F), but it predicts much slower FRETr recovery than is actually seen (Fig. 9 E). Note that these calculations include the effects of 6,000 µm−2

This revealed difficulties. Consider the concentration–response relations for Oxo-M inhibition of KCNQ current (data points in Fig. 9 C). The model for G protein activation by receptors and for G protein interaction with PLC is already known to give appropriate concentration–response relations for the early signaling steps (Falkenburger et al., 2010). Hence, it was unexpected that the model did very poorly with the low-concentration responses of the later signaling steps. For KCNQ current, it predicted too much suppression at low Oxo-M concentrations (0.001–1 µM; Fig. 9 C, red solid line). We discuss possible reasons for this discrepancy in the Discussion and show one possible solution here as the green dashed line in Fig. 9 (A–C). In this simulation, the synthesis of new PIP2 is accelerated several-fold during the Oxo-M application as several authors have already suggested (see Discussion and legend to Fig. 9). Accelerated synthesis counters the PIP2 depletion catalyzed by weak activation of PLC.

Finally, we considered the actions of Oxo-M on FRET from PH domain probes. The unchanged model (red solid lines) simulates the decrease of FRETr with 10 µM Oxo-M well (Fig. 9 D), and the concentration–response curve moderately well (Fig. 9 F), but it predicts much slower FRETr recovery than is actually seen (Fig. 9 E). Note that these calculations include the effects of 6,000 µm−2
Gating of KCNQ2/3 current by PIP2

Activation of Dr-VSP reduces PIP2 rapidly. KCNQ2/3 current responds to VSP activations as short as 40 ms, even before the sensing charge movement has finished. The rapidity of the inhibition means that PIP2 exchange at KCNQ2/3 channels is fast. In our earlier models (e.g., Suh et al., 2004), the residence time of PIP2 on a channel subunit was set at 4 s, but we had little evidence to go on. The VSP result here shows that 4 s is much too long because channel inhibition reaches a new steady level within tens of milliseconds after each VSP activation (Fig. 3 C). In the revised model, the residence time of PIP2 is 10 ms. It could be made shorter but not much longer. Apparently, the turnover time of PIP2 lipids on KCNQ subunits is shorter than the macroscopic gating times of the channel and is more on a timescale appropriate to underlie open–close transitions at the single-channel level, as was assumed by Park et al. (2005). This conclusion is predicated on the assumption that PIP2 of PH domains (Falkenburger et al., 2010) that are buffering the PIP2 as fast as it is made. It is our working hypothesis that in these cells that have been overexpressing PH domain probes as PIP2 buffers for 2 d, the activity of phosphoinositide-metabolizing enzymes has become augmented by compensatory gene expression. The blue dotted lines show much improvement in fitting the data from assuming that the 4- and 5-kinases and -phosphatases of these cells are augmented 10-fold. Such elevated rates are not appropriate for cells without PH domain expression and, for example, would predict recovery of current after Oxo-M in <20 s.

**Discussion**

We have completed a kinetic model of M1R signaling, spanning from the binding of agonist to receptor through G proteins and PLC to PIP2 depletion and resynthesis. The steps involving receptor and G proteins are described in our companion paper (Falkenburger et al., 2010), and this work adds phosphoinositide metabolism and the gating of KCNQ2/3 current by PIP2, with aspects of kinase regulation still unresolved. Our experiments lead to several model-independent conclusions. Principal among them are: (1) PIP2 interaction with KCNQ channels occurs in the millisecond timescale, (2) more than one bound PIP2 is needed for optimal activation of KCNQ channels, and (3) PIP2 recovery after VSP activation is much faster than after PLC activation.

Gating of KCNQ2/3 current by PIP2

Activation of Dr-VSP reduces PIP2 rapidly. KCNQ2/3 current responds to VSP activations as short as 40 ms, even before the sensing charge movement has finished. The rapidity of the inhibition means that PIP2 exchange at KCNQ2/3 channels is fast. In our earlier models (e.g., Suh et al., 2004), the residence time of PIP2 on a channel subunit was set at 4 s, but we had little evidence to go on. The VSP result here shows that 4 s is much too long because channel inhibition reaches a new steady level within tens of milliseconds after each VSP activation (Fig. 3 C). In the revised model, the residence time of PIP2 is 10 ms. It could be made shorter but not much longer. Apparently, the turnover time of PIP2 lipids on KCNQ subunits is shorter than the macroscopic gating times of the channel and is more on a timescale appropriate to underlie open–close transitions at the single-channel level, as was assumed by Park et al. (2005). This conclusion is predicated on the assumption that PIP2
must dissociate from channel subunits before VSP can cleave the 5-phosphate. Given that the PIP₂ binding site at VSP is buried in the enzyme molecule (Okamura et al., 2009), this assumption appears reasonable.

Recovery of PIP₂ and current after VSP activation was slow enough (10–20 s) to assume that KCNQ₂/₃ channels remain near equilibrium with PIP₂ throughout as the PIP₂ is restored gradually. The nonlinear relationship of KCNQ₂/₃ current to PH probe FRET indicates that current behaves like the square of the PH probe FRET and explains why KCNQ₂/₃ current turns off faster than PH probe FRET during PIP₂ depletion. Such an accelerated turn-off might be biologically relevant as a way to speed the loss of KCNQ₂/₃ current and the increase of neuronal excitability in response to receptor activation. The cooperativity in PIP₂ activation of KCNQ₂/₃ channels seen here in intact cells is consistent with Hill coefficients in the range of 1.35 to 1.9 for current activation obtained by application of (short-chain) diC₆-PIP₂ to excised inside-out membrane patches (Zhang et al., 2003; Li et al., 2005).

Very few KCNQ₂/₃ channels are needed to measure PIP₂—only around four channels µm⁻² in our cells, based on whole cell current, open probability, and single-channel conductance (see also Zaika et al. 2008). That small number would not perturb the cellular PIP₂ pools; however, Zaika et al. (2008) report that for every electrophysiologically functional KCNQ channel, there can be many additional channels in the plasma membrane that do not contribute to current. Quite likely they would also bind PIP₂. In contrast, PH probes require a high density to work as FRET reporters (Fig. S3 B): 1,700–3,000 µm⁻² for each PH probe (PH-CFP and PH-YFP) as determined by FRET efficiency and fluorescence intensity (Falkenburger et al., 2010). The pool of PIP₂ bound to the two PH probes is thus significant as compared with the pool of free PIP₂, which we take to be 5,000 µm⁻². This can alter phosphoinositide dynamics, as we and others find (Holz et al., 2000; Raucher et al., 2000; Lei et al., 2001; Várnai et al., 2002; Gamper et al., 2004; Szentpetery et al., 2009). The inhibition of KCNQ₂/₃ current by M₃R activation was slower, and the recovery faster, in cells with PH probe expression (Fig. 7 in Jensen et al., 2009). The slower onset of current inhibition with PH probe expression is reproduced by the model (not depicted). It is explained by buffering of PIP₂ by PH probes providing a reserve of PIP₂ to be hydrolyzed; however, our model does not predict a faster recovery of KCNQ₂/₃ current with PH probe expression unless the rates of some steps are modified. It also does not reproduce a relatively fast recovery of PH probe FRET seen after M₃R activation (Jensen et al., 2009). Such deviations from our simple predictions suggest that chronic expression of PH probes induces compensatory changes in phosphoinositide metabolism (see below).

**Phosphoinositide pools**

Full interpretation of phosphoinositide kinetics is limited by uncertainty about the absolute endogenous levels of different phosphoinositide lipids and the enzymes that act on them at the plasma membrane and in other membranes. We begin with the lipids.

Even for PIP₂, the density at the plasma membrane remains uncertain. McLaughlin et al. (2002) and Golebiowska et al. (2008) suggest an effective free concentration of 10 µM referred to total cell volume, which is equivalent to ~10,000 µm⁻² at the membrane for the 10-µm diameter cell they had in mind. Xu et al. (2003) give 4,000 µm⁻², and Hilgemann (2007) suggests values of 20,000–60,000 µm⁻². These estimates include potential errors in determining the total lipid content of a sample, the count of cells in the sample, and the plasma membrane area of each cell. According to measurements of PIP₂ diffusion by fluorescence correlation spectroscopy (Golebiowska et al., 2008), only one third of all PIP₂ (the 10 µM above) is free, and two thirds is reversibly bound to membrane proteins with an exchange time of ~10 ms. In all our calculations, we assume that reactions of probes and enzymes like PIP₂ 5-phosphatase and PLC are restricted to free PIP₂ molecules. Here and before (Suh et al., 2004), we have assumed 5,000 free PIP₂ µm⁻² in our modeling. This number would be compatible with the observation that ~50% of PH domains are bound to the plasma membrane and 50% are in the cytosol (Stauffer et al., 1998; van der Wal et al., 2001; Xu et al., 2003; Horowitz et al., 2005; Winks et al., 2005), with the following two assumptions: the in vitro dissociation constants for the binding of PIP₂ and of IP₃ to PH domains are valid, and the resting IP₃ concentration in the cell is 0.16 µM (Fink et al., 1999; Xu et al., 2003; Winks et al., 2005; see Fig. S3 A). Had we assumed a high PIP₂ density (20,000–60,000 µm⁻²), the expression of a pair of PH probes at 1,700–3,000 µm⁻² each would have had little impact on PIP₂ dynamics, so we consider this discrepancy as an argument against such high densities.

Biochemical measurements of PI and PI(4)P are even more difficult to interpret. Where are the pools of these PIP₂ precursors, how big are they, and where are the enzymes that act on them? The total cellular content of PI(4)P is similar to that of PIP₂ (Williams et al., 1998; Naisushoglu et al., 2002; Horowitz et al., 2005). We have suggested before that the pool of PI(4)P that is accessible to PLC during a 60-s M₃R activation (88% of the total) might all be at the plasma membrane (Horowitz et al., 2005). However, lipid trafficking from cytosolic vesicles to the plasma membrane might be fast enough (t½ ≈ 2 min; Maxfield and McGraw, 2004) to confound this concept. Some studies support the assumption that the majority of PI(4)P is at the plasma membrane (Hammond et al., 2009), but this could contradict the notion that PI(4)P is the characteristic phosphoinositide
of the Golgi complex and secretory vesicles. Endogenous PI 4-kinase activity is primarily associated with Golgi membranes, and overexpressed, fluorescently tagged type III PI 4-kinases localize primarily to ER and Golgi, but not to the plasma membrane (Cockcroft et al., 1985; Zhao et al., 2001; Wenk and De Camilli, 2004; Balla, 2007). Further, phosphoinositide transport proteins have been found necessary for sustained IP₃ generation in HL60 cells (Cunningham et al., 1995). These findings suggest that levels of PI(4)P at the plasma membrane might be low (<88% of total PI(4)P), and that transfer of PI(4)P between membrane compartments might be rapid. However, no phosphoinositide transport proteins have been reported for PI(4)P so far. (Phosphoinositide transport proteins might also act as cofactors for lipid kinases at the plasma membrane; Wirtz, 1997.)

Our kinetic model contains a single pool of PI(4)P in the same kinetic compartment as PIP₂. We have determined relative reaction fluxes from our time courses but have to remain skeptical about the absolute rate constants and absolute fluxes as long as the size and distribution of the PI(4)P pool(s) are unknown. Perhaps it is more realistic to represent the PI(4)P pool as several compartments connected by transport steps and to reinterpret the “synthesis” of PI(4)P by step 4-Ｋ in the model as including influx of PI(4)P from other compartments.

Metabolism of phosphoinositides

Ci-VSP has been shown to act as a PIP 5-phosphatase, both by biochemical assays and by monitoring PIP₂ and PI(4)P with fluorescent probes (Iwasaki et al., 2008; Halaszovich et al., 2009), implying that Dr-VSP also would act as a PIP 5-phosphatase. This is consistent with our observations that overexpression of PIP 5-kinase makes VSP activation less effective in suppressing current, requiring stronger depolarization to produce the same effect, and that recovery after VSP activation is speeded by overexpression of the PIP 5-kinase. VSP-sensing currents suggest that 13,000 VSP molecules are expressed per μm² of membrane, 50% of which are activated at +100 mV. As the number of activated VSP molecules (6,500 μm⁻²) may surpass that of PIP₂ molecules, VSP might “deplete” all PIP₂ simply by binding them before completing a full cycle of enzymatic activity. Thus, the rapid burst of current inhibition by VSP might overestimate the maximum velocity of steady-state VSP action. In our model, the initial P₂ consumption rate for VSP (at +100 mV) is 28,000 s⁻¹·μm⁻². For comparison, the cleavage rate with endogenous PLC during M₃R activation is 35-fold slower in the model, around 800 s⁻¹·μm⁻². The few PLC molecules (10 μm⁻²) would have to undergo many turnover cycles to deplete PIP₂ over the course of a few seconds.

Because VSP is a 5-phosphatase, recovery of PIP₂ and KCNQ current is governed by cellular PI(4)P 5-kinases. All of the depolarization-induced 5-phosphatase activity has to be from the plasma membrane VSP that the patch clamp voltage controls. Therefore, at least the PI(4)P generated by VSP activity and the PIP 5-kinase needed for rapid (few seconds) dephosphorylation should be in the plasma membrane. The chosen 5-kinase rate constant (0.02 s⁻¹), which depends on our assumption of initial plasma membrane PI(4)P, is in a similar range as in previous models (0.045 s⁻¹ in Horowitz et al., 2005; 0.048 s⁻¹ in Xu et al., 2003).

The 5-kinase could be regulated. M₃R activation can activate Rho kinase (Dutt et al., 2002), and several studies have shown stimulation of PIP 5-kinases by Rho family kinases and other signaling events (for review see Oude Weernink et al., 2004; Santarius et al., 2006; Mao and Yin, 2007). Measuring lipid and IP₃ turnover in response to muscarinic agonists, Willars et al. (1998) found: (1) both PIP₂ and PI(4)P are depleted quickly (as we also found; Horowitz et al., 2005), (2) yet IP₃ continues to be made in long stimulations, and (3), surprisingly, PIP₂ recovers before PIP₂. The more rapid recovery of PIP₂ might be explained by strong transient stimulation of PIP 5-kinase (and not the 5-phosphatase) during the recovery period. The extensive depletion of PI(4)P during receptor activation has at least two possible explanations. Accelerated 5-kinase could be converting the PI(4)P pool to PIP₂ that is then cleaved by PLC, or PLC might accept PI(4)P as a substrate in addition to PIP₂ (Wilson et al., 1984). Here, as before (Horowitz et al., 2005), our model assumes that PLC is able to cleave PI(4)P slowly (Table II), but we also suggest that speeding the 5-kinase during receptor activation helps explain the concentration–response relation for current (Fig. 9 C). Nevertheless, our measurements and modeling do not provide a clear preference for assuming that PLC does or does not cleave PI(4)P significantly. Removing the assumption forced changes in other rate constants but did not improve the fitting of, for example, the concentration–response curves.

Recovery after M₃R activation requires a wortmannin-sensitive (type III) PI 4-kinase (Suh and Hille, 2002; Zhang et al., 2003; Winks et al., 2005); therefore, we called the step that supplies PI(4)P at the membrane “4-Ｋ.” This step may also be accelerated by receptor activation. Stimulation of PI 4-kinase by receptor activation has been invoked in studies estimating IP₃ production (e.g., Cunningham et al., 1995; Willars et al., 1998; Xu et al., 2003; Brown et al., 2008) and by the failure of bradykinin and purinergic agonists to deplete PIP₂ despite activating PLC in neurons (Gamper et al., 2004; Zaika et al., 2007). We also suggest a faster rate for this step during Oxo-M than during recovery to reproduce our data with subsaturating Oxo-M (Fig. 9, A–C, green dashed lines; see also details in the legend). It would prevent low agonist concentrations from depleting PIP₂ excessively. If PI 4-kinase and PIP 5-kinase are stimulated...
by receptor activation, we do not know how long that effect lasts after agonist is removed. Hence, our estimates of their rates after agonist removal may be imperfect. (We expect no acceleration of kinases by VSP activation.) Current recovery from agonist was faster after overexpression of PLC or PH probes (Jensen et al., 2009). In these cases, however, the speeding might represent compensatory gene expression.

What is the mechanism of receptor-induced stimulation of PI(4)P synthesis? The speeding of PI 4-kinase by bradykinin requires IP3-mediated calcium release and neuronal calcium sensor 1 (Gamper et al., 2004; Zaika et al., 2007). Calmodulin-like neuronal calcium sensor 1 binds to PI 4-kinase β (in the Golgi) and stimulates the 4-kinase activity when calcium is increased by receptor activation (Zhao et al., 2001; Koizumi et al., 2002; Pan et al., 2002; Winks et al., 2005). The stimulation can be so strong that PIP2 is not depleted despite PLC activation. It is possible that M1R activation, which makes a Ca2+ transient in tsA201 cells, stimulates PI 4-kinase I by a similar mechanism, but to a lesser extent. There might also be other messengers. If type III PI 4-kinases are located in the Golgi complex, it is possible that not the PI 4-kinase but the PI(4)P transport to the plasma membrane might be rate limiting and stimulated by receptor activation. Our model would not discriminate between the stimulation of PI 4-kinases and any other event that transiently increases plasma membrane PI(4)P. One such possibility is exocytosis. Secretory vesicles are thought to bear PI(4)P formed by PI 4-kinases in Golgi and by 5-phosphatases during endocytosis (De Matteis and Godi, 2004; Wenk and De Camilli, 2004; Balla et al., 2005). Exocytosis can increase upon stimulation of Goq-coupled receptors both by Ca2+ release and by activating PKC (e.g., Hille et al., 1999), and vesicle fusion with the plasma membrane would deliver PI(4)P to the plasma membrane.

The time course of Oxo-M effects on PH probe FRET was well reproduced with increased rates for PIP2 synthesis (Fig. 9, D–F, dotted traces). Interestingly, the acceleration had little effect on the depression of PH probe FRET by Oxo-M (Fig. 9, D and F, dotted line vs. solid line). The reason is that PH probe FRET also responds to production of a second ligand, IP3, whereas current depends only on PIP2.

We proposed receptor-induced acceleration of PIP2 synthesis in part to correct a discrepancy in the predicted agonist concentration-response curve and in part because it is frequently invoked in the literature. The discrepancy was that low concentrations of agonist suppressed currents too much in the model as if PLC were activated too strongly there. Now we suggest a second factor that is likely to contribute to this discrepancy as well. Strong stimulation of M1Rs in tsA cells invokes a Goq transient (via IP3) that accelerates PLC strongly in a positive feedback loop (Horowitz et al., 2005). In our model, PLC activity depends on Goq, but the Ca2+ dependence is omitted. At low agonist concentrations, the IP3 and Ca2+ positive feedback should be much less, so our model will overestimate the stimulation of PLC there. This defect cannot be modeled until we study how IP3 production, Ca2+ elevation, and feedback to PLC depend on receptor activation. At high agonist concentrations, the time it takes to produce a full Ca2+ elevation might also contribute to a small delay we see in the onset of current suppression after agonist application (Table I in Jensen et al., 2009).

Conclusions

We have constructed a kinetic model of phosphoinositide metabolism informed by new kinetic studies after rapid dephosphorylation of PIP2 by Dr-VSP. Although this model represents a substantial advance from the previous one, it also shows clearly where we have to learn more. We need better estimates of phosphoinositide amounts in different membrane compartments and to determine the extent to which compartments other than the plasma membrane are involved in M1R signaling and lipid dynamics. In particular, the step supplying PI(4)P at the plasma membrane remains elusive. It is possible that events other than phosphorylation of PI at the plasma membrane contribute to the timing. We have shown that the step synthesizing PIP2 from PIP is much faster than the preceding step that supplies PIP, and we have advanced understanding of how PIP2 binding allows KCNQ2/3 channels to open. More than one PIP2 is needed per channel, and the residence time on a channel subunit is <10 ms. This insight is valuable for using KCNQ2/3 current to monitor cellular PIP2 levels and might generalize to other PIP2-regulated ion channels. Finally, we have shown that the voltage regulation of VSP activity is fast and makes VSP a powerful tool for investigating and perturbing phosphoinositide physiology and metabolism.

We thank Yasushi Okamura for providing Ci-VSP and Dr-VSP, Erwin Neher and William Zagotta for commenting on the manuscript, Sharona E. Gordon for use of equipment, and Lea Miller for technical help.

**Figure S1.** VSP-sensing currents. tsA201 cells transfected with Dr-VSP or Ci-VSP were recorded in whole cell voltage clamp. (A) Response to a family of voltage steps from -60 to +140 mV. Capacitive and leak currents were subtracted by a p/5 procedure. (B) Charges for OFF sensing were normalized to maximum and fitted with a Boltzmann equation for six cells with Dr-VSP and three cells with Ci-VSP.

**Figure S2.** Currents in untransfected and KCNQ2/3-transfected cells. (A) Currents recorded in tsA201 cells (whole cell voltage clamp) by a family of voltage steps (C). Note the fast activation and some inactivation of endogenous currents. (Inset) Magnification of channel deactivation: tail currents are not resolved. (B) Currents recorded in cells transfected with KCNQ2 and KCNQ3 subunits. Note the slow current activation and slow deactivation (“tail current”). (D) Current-voltage relationship for 16 untransfected cells and 16–33 cells transfected with KCNQ2/3. Note that -40 mV is sufficient to activate KCNQ2/3 current, whereas endogenous current is not activated at -20 mV.
Figure S3. Relationship of FRETr and PIP2. (A) Binding of PH probes to the plasma membrane depends on [PIP2] and [IP3]. We used reported affinities of PH probe to PIP2 and IP3 (see Table II). Based on fluorescence intensity, we assume total PH probes equivalent to 6 μM in the cytosol (Fig. 3A in Falkenburger et al., 2010). Graph plots model predictions for PIP2-bound PH probe at the membrane (blue, left axis) and IP3-bound PH probe in the cytosol (green, right axis) given different values of PIP2 (bottom axis) and 0.16 μM IP3 (solid lines) or 0 μM IP3 (dotted lines). Unbound, cytosolic PH probes are shown in red and plotted on the right axis. Note that PIP2 binding to the plasma membrane is IP3 dependent. With 0.16 μM IP3, 5,000 μm²/μM2 PIP2 is required to bind 50% of PH probes (3,000 μm²/μM2) to the membrane. With 0 μM IP3, PH probes bind to the plasma membrane more easily. (B) In the concentration range of interest, FRETr efficiency depends only on the density of acceptor molecules (PH-YFP). FRETr efficiency for different densities of acceptor was calculated with equations from Fung and Stryer (1978). A more recent framework yielded similar numbers (Corry et al., 2005). R0 for CFP/YFP is 49 Å (Patterson et al., 2001). (C) Relationship between FRETr efficiency and FRETr (see Materials and methods). (D) Dependence of FRETr on [PIP2] calculated from A–C for 0.16 μM IP3 (solid line) and square of FRETr (dotted line), the estimate we used for modeling KCNQ2/3 current.
